World Organisation for Animal Health
Founded as OIE

WORLD ORGANISATION FOR ANIMAL HEALTH

MANUAL OF DIAGNOSTIC TESTS AND VACCINES FOR TERRESTRIAL ANIMALS

(mammals, birds and bees)

Volume 1, 2, 3,

2023

FOREWORD

The *Manual of Diagnostic Tests and Vaccines for Terrestrial Animals* (*Terrestrial Manual*) aims to prevent and control animal diseases, including zoonoses, to contribute to the improvement of animal health services world-wide and to allow safe international trade in animals and animal products. The principal target readership is laboratories carrying out veterinary diagnostic tests and surveillance, along with vaccine manufacturers and users, and regulatory authorities in Members. The main objective is to provide internationally agreed diagnostic laboratory methods and requirements for the production and control of relevant vaccines and other biological products.

This ambitious task has required the cooperation of highly renowned animal health specialists from many WOAH Members. The World Organisation for Animal Health (WOAH, founded as OIE), received the mandate from its Members to undertake this task on a global level. The main activities of the organisation, which was established in 1924, and in 2023 comprised 183 Members, are as follows:

1. To ensure transparency in the global animal disease and zoonosis situation.
2. To collect, analyse and disseminate scientific veterinary information on animal disease control methods.
3. To provide expertise and encourage international solidarity in the control of animal diseases.
4. Within its mandate under the WTO (World Trade Organization) Agreement on Sanitary and Phytosanitary Measures (SPS Agreement), to safeguard world trade by publishing health standards for international trade in animals and animal products.
5. To improve the legal framework and resources of national Veterinary Services.
6. To provide a better guarantee of the safety of food of animal origin and to promote animal welfare through a science-based approach.

The *Terrestrial Manual*, covering infectious and parasitic diseases of mammals, birds and bees, was first published in 1989. Each successive edition has extended and updated the information provided. This twelfth edition includes over 15 updated chapters. The structure of the edition remains unchanged: Part 1 contains ten introductory chapters that set general standards for the management of veterinary diagnostic laboratories and vaccine production facilities; Part 2 comprises specific recommendations and includes eight chapters of recommendations for validation of diagnostic tests and three chapters of recommendations for the manufacture of vaccines; Part 3 comprises chapters on WOAH listed diseases and other diseases of importance.

As a companion volume to the *Terrestrial Animal Health Code*, the *Terrestrial Manual* sets laboratory standards for all WOAH listed diseases as well as several other diseases of global importance. It describes the diagnostic tests available and fit for purpose, including those that are suitable for certifying individual animals prior to movement. The *Terrestrial Manual* has become widely adopted as a key reference book for veterinary laboratories around the world. Aquatic animal diseases are included in a separate *Aquatic Manual*.

The task of commissioning chapters and compiling the *Terrestrial Manual* was assigned to the WOAH Biological Standards Commission by the World Assembly of national Delegates. Manuscripts were requested from specialists (the WOAH designated experts at WOAH Reference Laboratories when relevant) in each of the diseases or the other topics covered. When needed, an *ad hoc* Group of experts was convened tasked with updating or developing a chapter. The chapters were reviewed and approved by the Biological Standards Commission for circulation to all WOAH Member Countries for review and comment. The Commission, elected every 3 years by the Assembly, took the resulting comments into consideration, often referring back to the contributors for further clarification, before

finalising the chapters and approving them for circulation a second time to all WOAH Members. The final texts were then presented for adoption by the Assembly at the General Session held in May each year.

The Standards presented in each chapter of the *Terrestrial Manual* are International Standards in accordance with the mandate of the WOAH as recognised by the WTO under the SPS Agreement, and considering their approval by the WOAH World Assembly.

A procedure for the official recognition of commercialised diagnostic tests, under the authority of the Assembly, was finalised in September 2004. Data are submitted using a validation template that was developed by the Biological Standards Commission. Submissions regarding terrestrial animal diseases are evaluated by appointed experts, who advise the Biological Standards Commission before the final opinion of the WOAH World Assembly is sought. All information on the submission of applications can be found on the WOAH website.

The *Terrestrial Manual* continues to expand and to extend its range of topics covered. In 2022, it was decided to no longer publish a paper edition of the *Terrestrial Manual*. The online version of the *Terrestrial Manual* is therefore the only valid version of the *Terrestrial Manual*. The *Terrestrial Manual* is available in English and Spanish on the WOAH website.

At the 89th General Session in May 2022, the World Assembly of Delegates adopted Resolution No. 10, recognising that "OIE" will be replaced by "WOAH" as part of a rebranding of the Organisation, which will be applied in future editions of the *Terrestrial Manual*.

WOAH Biological Standards Commission

June 2023

INTRODUCTION
(How to use this *Terrestrial Manual*)

- **Arrangement of the *Terrestrial Manual***

Part 1, the beginning of this *Terrestrial Manual,* contains ten introductory chapters that set general standards for the management of veterinary diagnostic laboratories and vaccine facilities.

Part 2 elaborates specific recommendations on topics, many of which are introduced in Part 1 such as validation of diagnostic tests and for the manufacture of vaccines. The Section also includes chapters that have been developed on topics such as biotechnology and antimicrobial susceptibility testing.

The main part of the *Terrestrial Manual* (Part 3) covers standards for diagnostic tests and vaccines for specific diseases listed in the WOAH *Terrestrial Animal Health Code* and other important diseases. The diseases are in alphabetical order, subdivided by animal host group. WOAH listed diseases are diseases that have the potential for very serious and rapid spread, irrespective of national borders. They have particularly serious socio-economic or public health consequences and are of major importance in the international trade of animals and animal products.

Three of the diseases in Section 3.10 are included in some individual species sections, but these chapters cover several host species and thus give a broader description. Some additional diseases that may also be of importance but that do not have a chapter in the *Terrestrial Code* are also included in Section 3.10. This section also includes some important zoonotic infections.

Although there is a list of contributors at the beginning of the *Terrestrial Manual*, the final responsibility for the content of the *Terrestrial Manual* lies with the World Assembly of WOAH.

- **Part 3: Format of the disease-specific chapters**

Each disease chapter includes a summary intended to provide information for veterinary officials and other readers who need a general overview of the tests and vaccines available for the disease. This is followed by a text giving greater detail for laboratory workers. In each disease chapter, Part A gives a general introduction to the disease, Part B deals with laboratory diagnosis of the disease, and Part C (where appropriate) with the requirements for vaccines or *in vivo* diagnostic biologicals. The information concerning production and control of vaccines or diagnostics is given as an example; it is not always necessary to follow these when there are scientifically justifiable reasons for using alternative approaches. Bibliographic references that provide further information are listed at the end of each chapter.

- **Table of tests available for each disease and their purpose**

It has been agreed to include in each disease-specific chapter a table of the diagnostic tests available and in use for the disease graded against six purposes. The purposes relate to Chapter 1.1.6 *Validation of diagnostic assays for infectious diseases of terrestrial animals*, which identifies six main purposes for which diagnostic tests may be carried out. The aim of the table is to give a concise guide (elaborated in the text of the chapter) as to which tests are appropriate for which purpose.

COMMON ABBREVIATIONS USED IN THIS *TERRESTRIAL MANUAL*

ABTS	2,2'-azino-di-(3-ethyl-benzthiazoline)-6-sulphonic acid	EMTM	Evans' modified Tobie's medium
AGID	Agar gel immunodiffusion	EYL	Earle's yeast lactalbumin (balanced salt solution)
ATCC[1]	American type culture collection	FAT	Fluorescent antibody test
BBAT	Buffered *Brucella* antigen test	FAVN	Fluorescent antibody virus neutralisation
BCIP	5-bromo-4-chloro-3-indolyl-phosphate	FBS	Fetal bovine serum
BFK	Bovine fetal kidney (cells)	FITC	Fluorescein isothiocyanate
BGPS	Beef extract-glucose-peptone-serum (medium)	FLK	Fetal lamb kidney (cells)
BHK	Baby hamster kidney (cell line)	FPA	Fluorescence polarisation assay
BLP	Buffered lactose peptone	***g***	Relative centrifugal force
BPAT	Buffered plate antigen test	GIT	Growth inhibition test
BSA	Bovine serum albumin	HA	Haemagglutination
BSF	Bovine serum factors	HAD	Haemadsorption
CAM	Chorioallantoic membrane	HBSS	Hanks' balanced salt solution
CAT	Card agglutination test	H&E	Haematoxylin & eosin (stain)
CEF	Chicken embryo fibroblast	HEP	High-egg-passage (virus)
CF	Complement fixation (test)	HEPA	High-efficiency particulate air (filter)
CFU	Colony-forming unit	HEPES	N-2-hydroxyethylpiperazine, N-2-ethanesulphonic acid (buffer)
CIEP	Counter immunoelectrophoresis	HI	Haemagglutination inhibition
CK	Calf kidney (cells)	HRPO	Horseradish peroxidase
CNS	Central nervous system	IB	Immunoblot test
CPE	Cytopathic effect	ICFTU	International complement fixation test unit
CPLM	Cysteine-peptone-liver infusion maltose (medium)	ICPI	Intracerebral pathogenicity index
CSY	Casein-sucrose-yeast (agar)	ID_{50}	Median infectious dose
Ct	cycle threshold (PCR tests)	IFA	Indirect fluorescent antibody (test)
DEAE	Diethylaminoethyl	IGRA	Interferon gamma release assay
DEPC	Diethylpyrocarbonate	IHA	Indirect haemagglutination
DIVA	Detection of infection in vaccinated animals	IPMA	Immunoperoxidase monolayer assay
DMEM	Dulbecco's modified Eagle's medium	IU	International units
DMSO	Dimethyl sulfoxide	IVPI	Intravenous pathogenicity index
DTH	Delayed-type hypersensitivity	LA	Latex agglutination
EDTA	Ethylene diamine tetra-acetic acid	LD	Lethal dose
EGTA	Ethylene glycol tetra-acetic acid	LEP	Low egg passage (virus)
EID	Egg-infective dose	LPS	Lipopolysaccharide
ELISA	Enzyme-linked immunosorbent assay	MAb	Monoclonal antibody

1 American Type Culture Collection, P.O. Box 1549, Manassas, Virginia 20108, United States of America.

MALDI TOF MS	Matrix assisted laser desorption ionisation time of flight mass spectrometry	PPD	Purified protein derivative
MCS	Master cell stock	MAT	Microscopic agglutination test
MDBK	Madin–Darby bovine kidney (cell line)	PHA	Passive haemagglutination (test)
MDT	Mean death time	PPLO	Pleuropneumonia-like organisms
MEM	Minimal essential medium	PRN	Plaque reduction neutralisation
MHC	Major histocompatibility complex	PSG	Phosphate-buffered saline glucose
MLST	Multi-locus sequence typing	RBC	Red blood cell
MLV	Modified live virus (vaccine)	RFLP	Restriction fragment length polymorphism
m.o.i.	multiplicity of infection	RK	Rabbit kidney
MSV	Master seed virus	RPM	Revolutions per minute
NI	Neutralisation index	RSA	Rapid serum agglutination
NBT	Nitro blue tetrazolium	RT-PCR	Reverse-transcriptase polymerase chain reaction
NPLA	Neutralising peroxidase-linked assay	SAN	Specific antibody negative
OD	Optical density	SAT	Serum agglutination test
OGP	1-octyl-beta-D-glucopyranoside (buffer)	SDS	Sodium dodecyl sulphate
OPD	Orthophenyldiamine (chromogen)	SOP	Standard operating procedure
OPG	Oxalase-phenol-glycerin (preservative solution)	SPF	Specific pathogen free
ORF	Open reading frame	SPG	Sucrose phosphate glutamic acid
PAGE	Polyacrylamide gel electrophoresis	SRBC	Sheep red blood cells
PAP	Peroxidase–antiperoxidase (staining procedure)	$TCID_{50}$	Median tissue culture infective dose
PAS	Periodic acid-Schiff (reaction)	TMB	Tetramethyl benzidine
PBS	Phosphate-buffered saline	TSI	Triple sugar iron (medium)
PCR	Polymerase chain reaction	VB	Veronal buffer
PD	Protective dose	VBS	Veronal buffered saline
PFGE	Pulsed field gel electrophoresis	Vero	African green monkey kidney (cells)
PFU	Plaque-forming unit	VN	Virus neutralisation

*
* *

GLOSSARY OF TERMS

The definitions given below have been selected and restricted to those that are likely to be useful to users of this WOAH Terrestrial Manual*.*

- **Absorbance or optical density**

Absorbance, also termed optical density (OD), describes the amount of light transmitted through a medium. Many assays are designed so that the absorbance is proportional to the amount of analyte. OD at a specific wavelength is determined with a spectrophotometer. It is calculated as OD = $\log_{10}$(incident light/transmitted light)

- **Accuracy**

Nearness of a test value to the expected value for a reference standard reagent of known activity or titre.

- **Anthroponosis**

Anthroponosis is an infection or disease that is transmissible from humans to animals under natural conditions.

- **Assay**

Synonymous with test or test method, e.g. enzyme immunoassay, complement fixation test or polymerase chain reaction tests.

- **Batch**

All vaccine or other reagent, such as antigen or antisera, derived from the same homogeneous bulk and identified by a unique code number.

- **Biohazard (CWA[1] 15793:2011)**

Potential source of harm caused by biological agents or toxins.

- **Biological agent (adapted from CWA 15793:2011)**

Any microorganism including those which have been genetically modified, cell cultures, and parasites, which may be able to provoke any infection, allergy, or toxicity in humans, animals or plants. *Note:* for the purpose of Biorisk Analysis, prions are regarded as biological agents.

- **Biosafety**

Laboratory biosafety describes the principles and practices for the prevention of unintentional exposure to biological materials, or their accidental release.

1 CWA: CEN Workshop Agreement (2011). CEN: European Committee for Standardization

- **Biosecurity**

Laboratory biosecurity describes the controls on biological materials within laboratories, in order to prevent their loss, theft, misuse, unauthorised access, or intentional unauthorised release.

- **Biorisk (CWA 15793:2011)**

Combination of the probability of occurrence of harm and the severity of harm where the source of harm is a biological agent or toxin. Note: the source of harm may be an unintentional exposure, accidental release or loss, theft, misuse, diversion, unauthorised access or intentional unauthorised release.

- **Biorisk analysis (adapted from WOAH *Terrestrial Animal Health Code*)**

The process composed of biohazard identification, biorisk assessment, biorisk management and biorisk communication.

- **Biorisk assessment (CWA 15793:2011)**

Process of evaluating the biorisks arising from biohazards, taking into account the adequacy of any existing controls, and deciding whether or not the biorisk(s) is acceptable.

- **Biorisk Managment Advisor (CWA 15793:2011)**

Individual who has expertise in the biohazards encountered in the organisation and is competent to advise top management and staff on biorisk management issues.

- **Biorisk Management (adapted from WOAH *Terrestrial Animal Health Code*)**

Process of identifying, selecting and implementing measures that can be applied to reduce the level of biorisk.

- **Biorisk Management System (CWA 15793:2011)**

Part of an organisation's management system used to develop and implement its biorisk policy and manage its biorisks.

- **Cell line**

A stably transformed line of cells that has a high capacity for multiplication *in vitro*.

- **Centrifugation**

Throughout the text, the rate of centrifugation has been expressed as the Relative Centrifugal Force, denoted by '***g***'. The formula is:

$$\frac{(\text{RPM} \times 0.10472)^2 \times \text{Radius (cm)}}{980} = g$$

where RPM is the rotor speed in revolutions per minute, and where Radius (cm) is the radius of the rotor arm, to the bottom of the tube, in centimetres.

It may be necessary to calculate the RPM required to achieve a given value of ***g***, with a particular rotor. The formula is:

$$\frac{\text{RPM} = \sqrt{g \times 980}\,/\text{Radius (cm)}}{0.10472}$$

- **Comparability**

The preferred term when performance characteristics of a new test, which has undergone a minor change, are as good as those of a validated test within statistically defined limits.

- **Cross-reaction**

See False-positive reaction.

- **Ct value**

The number of amplification cycles in a real-time polymerase chain reaction (PCR) required for fluorescent signal to exceed the background.

- **Cut-off/threshold**

In immunoassays, cut-off or threshold values are those selected for distinguishing between negative and positive test results, and may include an indeterminate or suspicious zone.

- **Dilutions**

Where dilutions are given for making up liquid reagents, they are expressed as, for example, 1 in 4 or 1/4, meaning one part added to three parts, i.e. a 25% solution of A in B.

a) v/v – This is volume to volume (two liquids).

b) w/v – This is weight to volume (solid added to a liquid).

- **Dilutions used in virus neutralisation tests**

There are two different conventions used in expressing the dilution used in virus neutralisation (VN) tests. In Europe, it is customary to express the dilution before the addition of the antigen, but in the United States of America and elsewhere, it is usual to express dilutions after the addition of antigen.

These alternative conventions are expressed in the *Terrestrial Manual* as 'initial dilution' or 'final dilution', respectively.

- **Efficacy**

Specific ability of the biological product to produce the result for which it is offered when used under the conditions recommended by the manufacturer.

- **False-negative reaction**

Negative reactivity in an assay of a test sample obtained from an animal exposed to or infected with the organism in question, may be due to lack of analytical sensitivity, restricted analytical specificity or analyte degradation, decreases diagnostic sensitivity.

- **False-positive reaction**

Positive reactivity in an assay that is not attributable to exposure to or infection with the organism in question, maybe due to immunological cross-reactivity, cross-contamination of the test sample or non-specific reactions, decreases diagnostic specificity.

- **Final product (lot)**

All sealed final containers that have been filled from the same homogenous batch of vaccine in one working session, freeze-dried together in one continuous operation (if applicable), sealed in one working session, and identified by a unique code number.

- **Harmonisation**

The result of an agreement between laboratories to calibrate similar test methods, adjust diagnostic thresholds and express test data in such a manner as to allow uniform interpretation of results between laboratories.

- **Incidence**

Estimate of the rate of new infections in a susceptible population over a defined period of time; not to be confused with prevalence.

- **In-house checks**

All quality assurance activities within a laboratory directly related to the monitoring, validation, and maintenance of assay performance and technical proficiency.

- **In-process control**

Test procedures carried out during manufacture of a biological product to ensure that the product will comply with the agreed quality standards.

- **Inter-laboratory comparison (ring test)**

Any evaluation of assay performance and/or laboratory competence in the testing of defined samples by two or more laboratories; one laboratory may act as the reference in defining test sample attributes.

- **Laboratory biosafety**

See Biosafety.

- **Laboratory biosecurity**

See Biosecurity.

- **Limit of detection (LOD)**

The LOD is the estimated amount of analyte in a specified matrix that would produce a positive result at least a specified per cent of the time and is a measure of the analytical sensitivity.

- **Master cell (line, seed, stock)**

Collection of aliquots of cells of defined passage level, for use in the preparation or testing of a biological product, distributed into containers in a single operation, processed together and stored in such a manner as to ensure uniformity and stability and to prevent contamination.

- **Master seed (agent, strain)**

Collection of aliquots of an organism at a specific passage level, from which all other seed passages are derived, which are obtained from a single bulk, distributed into containers in a single operation and processed together and stored in such a manner as to ensure uniformity and stability and to prevent contamination.

- **Methods comparison (equivalency testing)**

Determination of certain assay performance characteristics of new or different test methods by means of an inter-laboratory comparison to a standard test method; implied in this definition is that participating laboratories are using their own test methods, reagents and controls and that results are expressed qualitatively.

- **Optical density**

See absorbance.

- **Performance characteristic**

An attribute of a test method that may include analytical sensitivity and specificity, accuracy and precision, diagnostic sensitivity and specificity and/or repeatability and reproducibility.

- **Phylogeography**

Phylogeography is the study of the genetic and geographic structure of populations and species.

- **Potency**

The potency of a biological product is the concentration of the immunologically active component. For a vaccine it is the concentration of the specific immunogen, and for an antiserum it is the concentration of the specific antibody.

- **Precision**

The degree of dispersion (variance, standard deviation or coefficient of variation) within a series of measurements of the same sample tested under specified conditions.

- **Predictive value (negative)**

The probability that an animal is free from infection given that it tests negative; predictive values are a function of the DSe (diagnostic sensitivity) and DSp (diagnostic specificity) of the diagnostic assay and the prevalence of infection.

- **Predictive value (positive)**

The probability that an animal has been infected given that it tests positive; predictive values are a function of the DSe and DSp of the diagnostic assay and the prevalence of infection.

- **Prevalence**

Estimate of the proportion of infected animals in a population at one given point in time; not to be confused with incidence.

- **Primary cells**

A pool of original cells derived from normal tissue up to and including the tenth subculture.

- **Production seed**

An organism at a specified passage level that is used without further propagation for initiating preparation of a production bulk.

- **Proficiency testing**

One measure of laboratory competence derived by means of an inter-laboratory comparison; implied in this definition is that participating laboratories are using the same test methods, reagents and controls and that results are expressed qualitatively.

- **Purity**

Quality of a biological product prepared to a final form and:

a) Relatively free from any extraneous microorganisms and extraneous material (organic or inorganic) as determined by test methods appropriate to the product; and

b) Free from extraneous microorganisms or material which could adversely affect the safety, potency or efficacy of the product.

- **Qualitative Risk Assessment (*Terrestrial Animal Health Code*)**

An assessment where the outputs of the likelihood of the outcome or the magnitude of the consequences are expressed in qualitative terms such as high, medium, low or negligible.

- **Quantitative Risk Assessment (*Terrestrial Animal Health Code*)**

An assessment where the outputs of the of the risk assessment are expressed numerically.

- **Receiver operator characteristic (ROC)**

ROC analysis provides a cut-off-independent approach for evaluation of the global accuracy of a test where results are measured as ordinal or continuous values. The area under the ROC curve provides a single numerical estimate of overall accuracy ranging from 0.5 (useless test) to 1 (perfect test).

- **Reference Laboratory**

Laboratory of recognised scientific and diagnostic expertise for a particular animal disease or testing methodology; includes capability for characterising and assigning values to reference reagents and samples.

- **Repeatability**

Level of agreement between replicates of a sample both within and between runs of the same test method in a given laboratory.

- **Reproducibility**

Ability of a test method to provide consistent results when applied to aliquots of the same sample tested by the same method in different laboratories.

- **Risk (*Terrestrial Animal Health Code*)**

The likelihood of the occurrence and the likely magnitude of the biological and economic consequences of an adverse event or effect to animal or human health.

- **Risk communication (*Terrestrial Animal Health Code*)**

The interactive transmission and exchange of information and opinions throughout the risk analysis process concerning risk, risk-related factors and risk perceptions among risk assessors, risk managers, risk communicators, the general public, and other interested parties.

- **Robustness**

Robustness refers to an assay's capacity to remain unaffected by minor variations in test situations that may occur over the course of testing.

- **Room temperature**

The term 'room temperature' is intended to imply the temperature of a comfortable working environment. Precise limits for this cannot be set, but guiding figures are 18–25°C. Where a test specifies room temperature, this should be achieved, with air conditioning if necessary; otherwise the test parameters may be affected.

- **Safety**

Freedom from properties causing undue local or systemic reactions when used as recommended or suggested by the manufacturer and without known hazard to in-contact animals, humans and the environment.

- **Sample**

Material that is derived from a specimen and used for testing purposes.

- **Sensitivity (analytical)**

Synonymous with 'Limit of Detection', smallest detectable amount of analyte that can be measured with a defined certainty; analyte may include antibodies, antigens, nucleic acids or live organisms.

- **Sensitivity (diagnostic)**

Proportion of known infected reference animals that test positive in the assay; infected animals that test negative are considered to have false-negative results.

- **Sensitivity (relative)**

Proportion of reference animals defined as positive by one or a combination of test methods that also test positive in the assay being compared.

- **Seroconversion**

i) Demonstration of a change from a seronegative to a seropositive condition using a serological assay specific for the antigen

OR

ii) Demonstration of a four-fold or more rise in antibody titre between an acute and convalescent serum using an ordinal test specific for the antigen.

- **Specific antibody negative (SAN)**

Used in relation to animals that have been shown by the use of appropriate tests to be free from antibodies to specific pathogenic microorganisms, and also eggs derived from SAN birds.

- **Specific pathogen free (SPF)**

Animals that have been shown by the use of appropriate tests to be free from specified pathogenic microorganisms, and also refers to eggs derived from SPF birds.

- **Specificity (analytical)**

Degree to which the assay distinguishes between the target analyte and other components in the sample matrix; the higher the analytical specificity, the lower the level of false-positives.

- **Specificity (diagnostic)**

Proportion of known uninfected reference animals that test negative in the assay; uninfected reference animals that test positive are considered to have false-positive results.

- **Specificity (relative)**

Proportion of reference animals defined as negative by one or a combination of test methods that also test negative in the assay being compared.

- **Specimen**

Material submitted for testing.

- **Standard Reagents**

  - **International Standard Reagents**

    Standard reagents by which all other reagents and assays are calibrated; prepared and distributed by an International Reference Laboratory.

  - **National Standard Reagents**

    Standard reagents calibrated by comparison with International Standard Reagents; prepared and distributed by a National Reference Laboratory.

- **Working Standards (reagents)**

  Standard reagents calibrated by comparison with the National Standard Reagent, or, in the absence of a National Standard Reagent, calibrated against a well-characterised in-house standard reagent; included in routine diagnostic tests as a control and/or for normalisation of test results.

- **Sterility**

Freedom from viable contaminating microorganisms, as demonstrated by approved and appropriate tests.

- **Test method**

Specified technical procedure for detection of an analyte (synonymous with assay).

- **Tests**

  - **Screening**

    Tests of high diagnostic sensitivity suitable for large-scale application.

  - **Confirmatory**

    Test methods of high diagnostic specificity that are used to confirm results, usually positive results, derived from other test methods

- **Thermotolerant**

For vaccines, the term is used to describe the ability to retain protective immunogenicity after exposure to temperatures above the storage temperature required according to the manufacturer's recommendations. Claims of thermotolerance must be supported by data.

- **Vaccine**

Includes all products designed to stimulate active immunisation of animals against disease, without regard to the type of microorganism or microbial component or toxin from which they may be derived or that they contain.

- **Validation**

Is a process that determines the fitness for purpose of an assay, which has been properly developed, optimised and standardised, for an intended use.

- **Working seed**

Organism at a passage level between master seed and production seed.

NB: FIRST ADOPTED IN 1996. MOST RECENT UPDATES ADOPTED IN 2023.

CONTRIBUTORS

CONTRIBUTORS AND PROFESSIONAL ADDRESS AT TIME OF WRITING

The chapters in the Terrestrial Manual *are prepared by invited contributors* (*WOAH Reference Experts, where possible*). *In accordance with WOAH standard procedure, all chapters are circulated to WOAH Members for comment. The WOAH Biological Standards Commission and the Consultant Editor then modify the text to take account of comments received, and the text is circulated a second time as the final version that will be presented for adoption by the World Assembly of Delegates to WOAH at the General Session in May of each year. The* Terrestrial Manual *is thus deemed to be a WOAH Standard that has come into being by international agreement. For this reason, the names of the contributors are not shown on individual chapters but are listed below. The Biological Standards Commission greatly appreciates the work of the following contributors* (*address at the time of writing*):

1.1.1. Management of veterinary diagnostic laboratories	**Dr T. Drew (retired)** Australia.
1.1.2. Collection, submission and storage of diagnostic specimens	**WOAH *ad hoc* Group on Biosafety and Biosecurity in Veterinary Laboratories**
1.1.3. Transport of biological materials	**WOAH *ad hoc* Group on Transport of Biological Materials**
1.1.4. Biosafety and biosecurity: standard for managing biological risk in the veterinary laboratory and animal facilities	**WOAH *ad hoc* Group on Biosafety and Biosecurity in Veterinary Laboratories**
1.1.5. Quality management in veterinary testing laboratories	**Dr A. Colling** Australian Centre for Disease Preparedness, CSIRO, Geelong, Victoria, Australia.
1.1.6. Validation of diagnostic assays for infectious diseases of terrestrial animals	**Dr A. Colling** Australian Centre for Disease Preparedness, CSIRO, Geelong, Victoria, Australia. **Dr I. Gardner (retired)** Canada
1.1.7. Standards for high throughput sequencing, bioinformatics and computational genomics[1]	**Dr S. Belak (retired) & Dr F. Granberg** Swedish University of Agricultural Sciences, Department of Biomedical Sciences and Veterinary Public Health, Uppsala, Sweden.
1.1.8. Principles of veterinary vaccine production	**WOAH Collaborating Centre for Veterinary Medicinal Products, Anses Fougères, France**

1 This chapter was updated by consensus of the WOAH *ad hoc* Group on High Throughput Sequencing, Bioinformatics and Computational Genomics.

1.1.9. Tests for sterility and freedom from contamination of biological materials intended for veterinary use	**Dr A. Colling & Dr K. Newberry** Australian Centre for Disease Preparedness, CSIRO, Geelong, Victoria, Australia.
1.1.10. Vaccine banks	**Dr A.-E. Füssel (retired)** Belgium. **Dr D. Mackay (retired)** UK. **Dr P.V. Barnett (retired)** UK.
2.1.1. Laboratory methodologies for bacterial antimicrobial susceptibility testing	**Dr D. White** US Food and Drug Administration, Center for Veterinary Medicine, Office of Research, Laurel, Maryland, USA.
2.1.2. Biotechnology advances in the diagnosis of infectious diseases	**Dr S. Belak (retired)**[2] Sweden.
2.1.3. Managing biorisk: examples of aligning risk management strategies with assessed biorisks	**WOAH *ad hoc* Group on Biosafety and Biosecurity in Veterinary Laboratories**
2.2.1. Development and optimisation of antibody detection assays *2.2.2. Development and optimisation of antigen detection assays* *2.2.3.Development and optimisation of nucleic acid detection assays* *2.2.4. Measurement uncertainty* *2.2.5. Statistical approaches to validation* *2.2.6. Selection and use of reference samples and panels* *2.2.7*. Validation of diagnostic tests for infectious diseases applicable to wildlife* *2.2.8. Comparability of assays after changes in a validated test method*	**WOAH *ad hoc* Group on Validation of Diagnostic Assays** ***WOAH *ad hoc* Group on Validation of Diagnostic Tests for Wildlife**
2.3.1. The application of biotechnology to the development of veterinary vaccines	**Dr A.A. Potter, Dr V. Gerdts, Dr G. Mutwiri, Dr S. Tikoo & De S. van Drunen Littel-van den Hurk** Vaccine and Infectious Disease Organization, Saskatoon, Canada.
2.3.2. The role of official bodies in the international regulation of veterinary biologicals	**Dr J.-P. Orand (retired) and Dr C. Lambert** Agence Nationale du Médicament Vétérinaire, Anses Fougères, France. **Dr B. Rippke (retired)** USA. **Dr T. Tsutsui** National Institute of Animal Health, Division of Viral Disease and Epidemiology, National Institute of Animal Health, Ibaraki, Japan.

2 This chapter was updated by consensus of an Expert Consultation

2.3.3. Minimum requirements for the organisation and management of a vaccine manufacturing facility	
2.3.4. Minimum requirements for the production and quality control of vaccines	**WOAH Collaborating Centre for Veterinary Medicinal Products, Anses Fougères, France**
2.3.5. Minimum requirements for aseptic production in vaccine manufacture	
3.1.1. Anthrax	**Dr K. Amoako** Canadian Food Inspection Agency, National Centre for Animal Disease (NCAD), Lethbridge Laboratory, Alberta, Canada. **Dr G. Harvey** USDA, APHIS, National Veterinary Services Laboratories, Ames, Iowa, USA.
3.1.2. Aujeszky's disease (*infection with Aujeszky's disease virus*)	**Dr A. Jestin & Dr M.F. Le Potier** Anses-Ploufragan, Laboratoire d'études et de recherches avicoles et porcines, Ploufragan, France. **Dr W. Loeffen** Wageningen Bioveterinary Research, Lelystad, The Netherlands. **Dr S.L. Swenson (formerly)** USDA, APHIS, National Veterinary Services Laboratories, Ames, Iowa, USA.
3.1.3. Bluetongue (*infection with bluetongue virus*)[3]	**Dr Debbie Eagles** Australian Centre for Disease Preparedness, CSIRO, Geelong, Victoria, Australia.
3.1.4. Brucellosis (*infection with* Brucella abortus, B. melitensis *and* B. suis)[4]	**Dr A. Whatmore** APHA Weybridge, New Haw, Addlestone, Surrey, Weybridge, UK.
3.1.5. Crimean–Congo haemorrhagic fever	**Dr J.C. Manuguerra** Institut Pasteur, Paris, France.
3.1.6. Echinococcosis (*infection with* Echinococcus granulosus and *with* E. multilocularis *virus*)	**Dr G. Masala** Istituto Zooprofilattico Sperimentale (IZS) of Sardinia, Sassari, Italy. **Dr M. Donadeu & Dr M. Lightowlers** Faculty of Veterinary and Agricultural Sciences, The University of Melbourne, Werribee, Australia.
3.1.7. Epizootic haemorrhagic disease (*infection with epizootic hemorrhagic disease virus*)	**Dr S. Zientara & Dr C. Sailleau** Laboratoire de santé animale de Maisons-Alfort, Maisons-Alfort, France.
3.1.8. Foot and mouth disease (*infection with foot and mouth disease virus*)[5]	**Dr D.J. King** The Pirbright Institute, Ash Road, Woking, Surrey, UK.

3 This chapter was updated by consensus of all WOAH Reference Laboratories for bluetongue.
4 This chapter was updated by consensus of all WOAH Reference Laboratories for brucellosis.
5 This chapter was updated by consensus of all WOAH Reference Laboratories for foot and mouth disease.

3.1.9. Heartwater	**Dr N. Vachiéry & Dr I. Marcelino** UMR CIRAD-INRA 117 ASTRE, Campus International de Baillarguet, Montpellier, France.
3.1.10. Japanese encephalitis	**Dr D.-K. Yang** Animal and Plant Quarantine Agency, Gyeongsangbuk-do, Korea (Rep. of).
3.1.11. Leishmaniosis	**Dr F. Vitale** Istituto Zooprofilattico Sperimentale della Sicilia, National Reference Centre for Leishmaniasis, Palermo, Italy.
3.1.12. Leptospirosis[6]	**Dr J. Petrakovsky** Laboratorio de Leptospirosis, Dirección General de Laboratorios y Control Técnico, Servicio Nacional de Sanidad y Calidad Agroalimentaria (SENASA), Martínez, Pcia de Buenos Aires, Argentina.
3.1.13. Mammalian tuberculosis (*infection with* Mycobacterium tuberculosis *complex*)	**WOAH *Ad hoc* Group on Replacement of the International Standard Bovine Tuberculin**
3.1.14. New World screwworm (Cochliomyia hominivorax) *and* Old World *screwworm* (Chrysomya bezziana)	**Dr J. Welch** COPEG (Panama–US Commission for the Eradication and Prevention of NWS), Panama, Panama. **Dr M.J.R. Hall** Department of Entomology, The Natural History Museum, Cromwell Road, London, UK.
3.1.15. Nipah and Hendra virus diseases	**Dr K. Halpin** Australian Centre for Disease Preparedness, CSIRO, Geelong, Victoria, Australia.
3.1.16. Paratuberculosis (*Johne's disease*)[7]	**Dr Bernardo Alonso** DILAB (Dirección de Laboratorios y Control Técnico), Servicio Nacional de Sanidad y Calidad, Agroalimentaria (SENASA), Martínez, Prov. de Buenos Aires, Argentina.
3.1.17. Q fever	**Dr E. Rousset & Dr K. Sidi-Boumedine** Anses Sophia Antipolis, Laboratoire d'Études et de Recherches sur les Petits Ruminants et les Abeilles, Sophia Antipolis Cedex, France. **Dr B. Kadra & Dr B. Kupcsulik** Ceva-Phylaxia Co. Ltd, Budapest, Hungary.
3.1.18. Rabies (*infection with rabies virus and other lyssaviruses*)[8]	**Dr T. Müller** Institute of Molecular Virology and Cell Biology, Friedrich-Loeffler Institut, Federal Research Institute for Animal Health, Insel Riems, Germany.

6 This chapter was updated by consensus of all WOAH Reference Laboratories for leptospirosis.
7 This chapter was updated by consensus of all WOAH Reference Laboratories for paratuberculosis.
8 This chapter was updated by consensus of all WOAH Reference Laboratories for rabies.

3.1.19. Rift Valley fever (*infection with Rift Valley fever virus*)[9]	**Dr C. Cetre-Sossah** Campus international de Baillarguet, Montpellier, France. **Dr B.A. Lubisi** Onderstepoort Veterinary Institute, Agricultural Research Council, Onderstepoort, South Africa.
3.1.20. Rinderpest (*infection with rinderpest virus*)	**Dr G. Libeau (retired)** France. **Dr M. Baron (retired)** UK. **Dr K. Yoshida** National Institute of Animal Health (NIAH), National Agriculture and Food Research Organization, Tokyo, Japan.
3.1.21. Surra in all species (Trypanosoma evansi *infection*)[10]	**Dr M. Desquesnes** UMR177-Intertryp (CIRAD-IRD), CIRAD-bios, Campus international de Baillarguet, Montpellier, France.
3.1.22. Trichinellosis (*infection with* Trichinella *spp.*)	**Dr B. Scandrett** Canadian Food Inspection Agency, Centre for Foodborne & Animal Parasitology, Saskatoon, Saskatchewan, Canada. **Dr M.A. Gomez Morales** Istituto Superiore di Sanita, Laboratorio di Parasitoligia, Roma, Italy
3.1.23. Tularemia	**Dr T.E. Rocke** USGS National Wildlife Health Center, Wisconsin, United States of America. **Dr M. Gyuranecz** Laboratory of Zoonotic Bacteriology and Mycoplasmology, Institute for Veterinary Medical Research, Centre for Agricultural Research, Hungarian Academy of Sciences, Budapest, Hungary.
3.1.24. Vesicular stomatitis	**Dr E.M. Pituco** PANAFTOSA, Rio de Janeiro, Brazil. **Dr M.K. Torchetti** USDA, APHIS, National Veterinary Services Laboratories, Ames, Iowa, USA.
3.1.25. West Nile fever	**Dr F. Monaco** Istituto Zooprofilattico Sperimentale dell'Abruzzo e del Molise "G. Caporale", Teramo, Italy. **Dr T. Sturgill** USDA, APHIS, National Veterinary Services Laboratories, Ames, Iowa, USA.

9 This chapter was updated by consensus of the WOAH *ad hoc* Group on Rift Valley fever.
10 This chapter was updated by consensus of the WOAH *ad hoc* Group on Diagnostic Tests for Trypanosomoses.

Introductory note on bee diseases	**Dr M.-P. Chauzat** Anses Sophia Antipolis, Bee Pathology Unit, Sophia Antipolis, France.
3.2.1. Acarapisosis of honey bees (*infestation of honey bees with* Acarapis woodi)	**Dr R. Hall** Diagnostic and Surveillance Services, Biosecurity New Zealand, Ministry for Primary Industries, Upper Hutt, New Zealand.
3.2.2. American foulbrood of honey bees (*infection of honey bees with* Paenibacillus larvae) *3.2.3. European foulbrood of honey bees* (*infection of honey bees with* Melissococcus plutonius)	**Dr K. Sidi-Boumedine** Anses Sophia Antipolis, Bee Pathology Unit, Sophia Antipolis, France.
3.2.4. Nosemosis of honey bees	**Dr I. Fries** Honey Bee Research Group, Department of Ecology, Swedish University of Agricultural Sciences, Uppsala, Sweden.
3.2.5. Infestation with Aethina tumida (*small hive beetle*) *3.2.6. Infestation with* Tropilaelaps *spp.*	**Dr M.-P. Chauzat, Dr S. Franco, Dr V. Duquesne & Dr M.-P. Rivière** Anses Sophia Antipolis, Bee Pathology Unit, Sophia Antipolis, France.
3.2.7. Varroosis of honey bees (*infestation of honey bees with* Varroa *spp.*)	**Dr M.O. Schäfer** National Reference Laboratory for Bee Diseases, Friedrich-Loeffler-Institut, Federal Research Institute for Animal Health, Insel Riems, Germany.
3.3.1. Avian chlamydiosis	**Dr C. Schnee** Institute of Molecular Pathogenesis, Friedrich-Loeffler-Institut, Federal Research Institute for Animal Health, Jena, Germany. **Prof. D. Vanrompay** Laboratory for Immunology and Animal Biotechnology, Department of Animal Production, Faculty of Bioscience Engineering, Ghent University, Coupure Links, Ghent, Belgium. **Dr K. Laroucau** Anses Maisons-Alfort, Animal Health Laboratory Bacterial Zoonoses Unit, Maisons-Alfort, France.
3.3.2. Avian infectious bronchitis	**Dr J.J. (Sjaak) de Wit** Department R&D, GD Animal Health, Deventer, The Netherlands. **Dr P. Britton** The Pirbright Institute, Compton Laboratory, Newbury, Berkshire, UK.
3.3.3. Avian infectious laryngotracheitis	**Dr A.H. Noormohammadi & Dr J. Devlin** Faculty of Veterinary Science, The University of Melbourne, Werribee, Victoria, Australia.

3.3.4. Avian influenza (*including infection with high pathogenicity avian influenza viruses*)[11]

Dr D. Swayne(retired)
Southeast Poultry Research Laboratory, Athens, Georgia, USA.

Prof. I. Brown
APHA Weybridge, New Haw, Addlestone, Surrey, Weybridge, UK.

3.3.5. Avian mycoplasmosis (Mycoplasma gallisepticum, M. synoviae)

Dr S. Catania
Mycoplasma Unit, Istituto Zooprofilattico Sperimentale delle Venezie, Verona, Italy

Dr Evelin Lobo Riveroi (formerly)
MYCOLAB Laboratorio para diagnóstico de micoplasmas, Centro Nacional de Sanidad Agropecuaria, San José de las Lajas, Provincia Mayabeque, Cuba.

3.6. Avian tuberculosis

Dr I. Pavlik (formerly) & Dr I. Slaná (formerly)
Veterinary Research Institute, Brno, Czech Republic.

3.3.7. Duck virus enteritis

3.3.8. Duck virus hepatitis

Dr S. Stoute
California Animal Health and Food Safety Laboratory System, University of California, Davis, California, USA.

3.3.9. Fowl cholera

Dr P. Blackall
Poultry Hub Australia, Queensland Alliance for Agriculture and Food Innovation, University of Queensland, EcoSciences Precinct, Brisbane, Queensland, Australia.

3.3.10. Fowlpox

Dr H.S. Sellers
Poultry Diagnostic and Research Center, Department of Population Health, College of Veterinary Medicine, University of Georgia, Athens, Georgia, USA.

3.3.11. Fowl typhoid and Pullorum disease

Dr R. Davies
APHA Weybridge, New Haw, Addlestone, Surrey, UK.

3.3.12. Infectious bursal disease (*Gumboro disease*)

Dr N. Eterradossi
Anses, Laboratoire de Ploufragan-Plouzané, Laboratoire d'études et de recherches avicoles, porcines et piscicoles, Ploufragan-Plouzané, France.

Dr Y. Saif
Food Animal Health Research Program, Ohio Agricultural Research and Development Center, Ohio State University, Wooster, Ohio, USA.

11 This chapter was updated by consensus of all WOAH Reference Laboratories for avian influenza.

3.3.13. Marek's disease

Dr Y. Yao & Dr V. Nair (retired)
The Pirbright Institute, Ash Road, Woking, Surrey, UK.

Dr J.R. Dunn
US National Poultry Research Center, USDA-ARS Southeast Poultry Research Laboratory, Athens, Georgia, USA.

3.3.14. Newcastle disease (infection with Newcastle disease virus)[12]

Dr D. Swayne (retired)
USA.

Prof. I. Brown
APHA Weybridge, New Haw, Addlestone, Surrey, Weybridge, UK.

3.3.15. Turkey rhinotracheitis (avian metapneumovirus)

Dr N. Eterradossi & Dr P. Brown
Anses, Laboratoire de Ploufragan-Plouzané, Laboratoire d'études et de recherches avicoles, porcines et piscicoles, Ploufragan-Plouzané, France.

3.4.1. Bovine anaplasmosis

Dr F. Parrodi (formerly) & Dr J.J. Mosqueda Gualito
Centro Nacional de Servicios de Constatación en Salud Animal (CENAPA), Morelos, Mexico.

3.4.2. Bovine babesiosis

Prof. N. Yokoyama
National Research Center for Protozoan Disease Obihiro University of Agriculture and Veterinary Medicine, Hokkaido, Japan.

Dr J.J. Mosqueda Gualito
Centro Nacional de Servicios de Constatación en Salud Animal (CENAPA), Morelos, Mexico.

3.4.3. Bovine cysticercosis

See chapter 3.10.3.

3.4.4. Bovine genital campylobacteriosis

Prof. J.A. Wagenaar & Dr L. van der Graaf-van Bloois
Department of Infectious Diseases and Immunology, Faculty of Veterinary Medicine, Utrecht University, Utrecht, The Netherlands.

3.4.5. Bovine spongiform encephalopathy[13]

Prof. T. Seuberlich
NeuroCentre, Department of Clinical Research and Veterinary Public Health, Division of Experimental Clinical Research, University of Bern, Bern, Switzerland.

3.4.6. Bovine tuberculosis

Dr D.V. Cousins (retired)
Australia.

3.4.7. Bovine viral diarrhoea[14]

Dr P. Kirkland
Elizabeth Macarthur Agriculture Institute (EMAI), Virology Laboratory, Menangle, Camden, New South Wales, Australia.

12 This chapter was updated by consensus of all WOAH Reference Laboratories for Newcastle disease.
13 This chapter was updated by consensus of all WOAH Reference Laboratories for bovine spongiform encephalopathy.
14 This chapter was updated by consensus of all WOAH Reference Laboratories for bovine viral diarrhoea.

3.4.8. Contagious bovine pleuropneumonia (*infection with* Mycoplasma mycoides *subsp.* mycoides)[15]	**Dr F. Thiaucourt (retired)** France.
3.4.9. Enzootic bovine leukosis	**Prof. T.W. Vahlenkamp** Institute of Virology, Centre for Infectious Diseases, Faculty of Veterinary Medicine, Leipzig University, Leipzig, Germany. **Dr B. Choudhury** APHA Weybridge, New Haw, Addlestone, Surrey, UK. **Dr J. Kuzmak** National Veterinary Research Institute, Pulawy, Poland.
3.4.10. Haemorrhagic septicaemia (Pasteurella multocida *serotypes 6:b and 6:e*)	**Dr S.B. Shivachandra** ICAR-National Institute of Veterinary Epidemiology and Disease Informatics (NIVEDI), Karnataka, India.
3.4.11. Infectious bovine rhinotracheitis/ infectious pustular vulvovaginitis	**Dr M. Beer** Institute of Diagnostic Virology, Friedrich-Loeffler-Institut, Federal Research Institute for Animal Health, Insel Riems, Germany. **Dr A. Dastjerdi** APHA Weybridge, New Haw, Addlestone, Surrey, UK.
3.4.12. Lumpy skin disease	**Dr P. Beard (formerly)** The Pirbright Institute, Ash Road, Woking, Surrey, UK. **Dr D. Wallace** Onderstepoort Veterinary Institute, Agricultural Research Council, Onderstepoort, South Africa.
3.4.13. Malignant catarrhal fever	**Dr G. Russell** Moredun Research Institute, International Research Centre, Pentlands Science Park, Penicuik, Scotland, UK.
3.4.14. Nagana: infections with salivarian trypanosomoses (*excluding* Trypanosoma evansi *and* T. equiperdum)[16]	**Dr M. Desquesnes** UMR177-Intertryp (CIRAD-IRD), CIRAD-bios, Campus international de Baillarguet, Montpellier, France.
3.4.15. Theileriosis in cattle (*infection with* Theileria annulata, T. orientalis *and* T. parva)	**Dr P. Toye** Animal Health and Genetics, International Livestock Research Institute, Nairobi, Kenya. **Dr D. Geysen** Institute of Tropical Medicine, Department of Animal Health, Antwerp, Belgium.

15 This chapter was updated by consensus of all WOAH Reference Laboratories for contagious bovine pleuropneumonia.

16 This chapter was updated by consensus of the following WOAH experts on trypanosomes: Dr L. Touratier (deceased), Prof. N. Inoue, Prof. Ph. Büscher, Dr K. Suganuma, Dr M. Gonzatti.

3.4.16. Trichomonosis	**Dr E. Authie (formerly)** Laboratoire National de Contrôle des Reproducteurs, Maisons-Alfort, France. **Prof. A. Lew-Tabor** The University of Queensland, St. Lucia, Brisbane Queensland, Australia. **Prof. I. Diallo** Biosecurity Sciences Laboratory, Health and Food Sciences Precinct, Brisbane, Queensland, Australia.
3.5.1. Camelpox	**Dr U. Wernery, Dr K. Kamal-Aldin, Mrs S. Joseph & Mrs A. Riya Thomas** Central Veterinary Research Laboratory, Dubai, United Arab Emirates.
2.5.2. Middle East respiratory syndrome (*infection of dromedary camels with MERS-CoV*)	**WOAH *ad hoc* Group on Middle East Respiratory Syndrome Coronavirus (MERS-Cov)**
3.6.1. African horse sickness (*infection with African horse sickness virus*)	**Prof. J.M. Sánchez-Vizcaíno** Centro de Vigilancia Sanitaria Veterinaria, Facultad de Veterinaria, Universidad Complutense de Madrid, Madrid, Spain. **Dr M. Agüero Garcia** Laboratorio Central de Veterinaria, Algete (Madrid), Spain. **Dr J. Baron Castillo-Olivares** The Pirbright Institute, Ash Road, Woking, Surrey, UK.
3.6.2. Contagious equine metritis	**Dr I. Mawhinney** APHA Bury St Edmunds, Suffolk, UK **Dr M.M. Erdman** USDA, APHIS, National Veterinary Services Laboratories, Ames, Iowa, USA.
3.6.3. Dourine in horses (Trypanosoma equiperdum *infection*)[17]	**Prof. Ph. Büscher (retired)** Belgium.
3.6.4. Epizootic lymphangitis	**Dr C. Scantlebury** Department of Functional and Comparative Genomics, Institute of Integrative Biology, Biosciences Building, University of Liverpool, UK.
3.6.5. Equine encephalomyelitis (*Eastern, Western and Venezuelan*)	**Dr T. Sturgill** USDA, APHIS, National Veterinary Services Laboratories, Ames, Iowa, USA.

17 This chapter was updated by consensus of the following WOAH experts on trypanosomes: Dr M.I. Gonzatti, Dr I. Pascucci, Dr L. Touratier (deceased), Dr M. Desquesnes, Dr A. Schnaufer, Dr K. Suganuma, Dr N. Inoue, Dr N. Van Reet, Dr N. Ledesma, Dr L. Hébert.

3.6.6. Equine infectious anaemia	**Dr E.N. Ostlund (retired)** USA. **Dr J. Zhou** Laboratory of Equine Infectious Anemia Harbin Veterinary Research Institute of Chinese Academy of Agricultural Sciences Harbin, China (People's Rep. of). **Dr K. Murakami** National Institute of Animal Health, Viral Disease Section, Ibaraki, Japan.
3.6.7. Equine influenza (*infection with equine influenza virus*)[18]	**Prof. A. Cullinane** Irish Equine Centre, Johnstown, Naas, Co. Kildare, Ireland.
3.6.8. Equine piroplasmosis	**Prof. N. Yokoyama** National Research Center for Protozoan Disease Obihiro University of Agriculture and Veterinary Medicine, Hokkaido Japan.
3.6.9. Equine rhinopneumonitis (*equine herpesvirus-1 and -4*)[19]	**Dr D. Elton & Dr N. Bryant** Animal Health Trust, Centre for Preventive Medicine, Kentford, Suffolk, UK.
3.6.10. Equine viral arteritis (*infection with equine arteritis virus*)	**Dr P.J. Timoney (retired)** USA. **Dr T. Drew & Prof. F. Steinbach** APHA Weybridge, New Haw, Addlestone, Surrey, UK.
3.611. Glanders and melioidosis	**Dr H. Neubauer** Institute of Bacterial Infections and Zoonoses, Friedrich-Loeffler Institut, Federal Research Institute for Animal Health, Jena, Germany. **Prof. U. Wernery** Central Veterinary Research Laboratory, Dubai, United Arab Emirates.
3.7.1. Myxomatosis *3.7.2. Rabbit haemorrhagic disease*	**Dr A. Lavazza, Dr L. Capucci & Dr P. Cavadini** Istituto Zooprofilattico Sperimentale della Lombardia e dell'Emilia Romagna, Brescia, Italy.
3.8.1. Border disease	**Dr P. Kirkland** Elizabeth Macarthur Agriculture Institute (EMAI), Virology Laboratory, Camden, New South Wales, Australia.
3.8.2. Caprine arthritis/encephalitis & Maedi-visna	**Dr D. Knowles (retired) & Dr L.M. Herrmann** USDA-ARS, Animal Disease Research Unit, Washington State University, Pullman, Washington, USA.

18 This chapter was updated by consensus of all WOAH Reference Laboratories for equine influenza.
19 This chapter was updated by consensus of all WOAH Reference Laboratories for equine rhinopneumonitis.

3.8.3. Contagious agalactia	**Dr R. Ayling** APHA Weybridge, New Haw, Addlestone, Surrey, UK. **Dr G. Loria** Istituto Zooprofilattico Sperimentale della Sicilia (IZSSi), Palermo, Italy.
3.8.4. Contagious caprine pleuropneumonia	**Dr F. Thiaucourt (retired)** France.
3.8.5. Enzootic abortion of ewes (*ovine chlamydiosis*) (*infection with* Chlamydophila abortus)	**Dr C. Schnee** Institute of Molecular Pathogenesis, Friedrich-Loeffler-Institut, Federal Research Institute for Animal Health, Jena, Germany. **Dr N. Borel** Institute for Veterinary Pathology, Vetsuisse Faculty, University of Zurich, Zurich, Switzerland. **Dr K. Laroucau** Anses Maisons-Alfort, Animal Health Laboratory Bacterial Zoonoses Unit, Maisons-Alfort, France.
3.8.6. Nairobi sheep disease	*See chapter 3.10.1.*
3.8.7. Ovine epididymitis (Brucella ovis)[20]	**Dr B. Garin-Bastuji (retired)** France. **Dr J.M. Blasco** Centro de Investigación y Tecnología Agroalimentaria de Aragón, Zaragoza, Spain.
3.8.8. Ovine pulmonary adenocarcinoma (*adenomatosis*)	**Dr M.J. Sharp (formerly)** APHA, Lasswade Laboratory, Pentlands Science Park, Bush Loan, Penicuik, Scotland, UK.
3.8.9. Peste des petits ruminants (*infection with small ruminant morbillivirus*)[21]	**Dr M. Baron (retired)** UK.
3.8.10. Salmonellosis (*S. abortusovis*)	*See chapter 3.10.7*
3.8.11. Scrapie[22]	**Dr J. Spiropoulos** APHA Weybridge, New Haw, Addlestone, Surrey, UK.
3.8.12. Sheep pox and goat pox	**Dr P. Beard (formerly)** The Pirbright Institute, Ash Road, Woking, Surrey, UK. **Dr B.A. Lubisi** Onderstepoort Veterinary Institute, Agricultural Research Council, Onderstepoort, South Africa. **Dr H. Reza Varshovi (retired)** Iran.

20 This chapter was updated by consensus of all WOAH Reference Laboratories for brucellosis and other experts.
21 This chapter was updated by consensus of all WOAH Reference Laboratories for peste des petits ruminants.
22 This chapter was updated by consensus of all WOAH Reference Laboratories for scrapie.

3.8.13 Theileriosis in sheep and goats (*infection with* Theileria lestoquardi, T. luwenshuni *and* T. uilenbergi)	**Dr A. Torina** Istituto Zooprofilattico Sperimentale della Sicilia (IZSSi), Palermo, Italy.
3.9.1. African swine fever	**Dr C.A.L. Oura (formerly)** The Pirbright Institute, Ash Road, Woking, Surrey, UK. **Dr M. Arias** Centro de Investigación en Sanidad Animal (CISA-INIA), Madrid, Spain.
3.9.2. Atrophic rhinitis of swine	**Dr K.B. Register** USDA, ARS, National Animal Disease Center, Ames, Iowa, USA.
3.9.3. Classical swine fever (*infection with classical swine fever virus*)[23]	**Prof. P. Becher** Department of Infectious Diseases, Institute of Virology, University of Veterinary Medicine of Hannover, Hannover, Germany.
3.9.4. Nipah virus encephalitis	*See chapter 3.1.14.*
3.9.5. Porcine cysticercosis (*infection with* Taenia solium)	*See chapter 3.10.3.*
3.9.6. Porcine reproductive and respiratory syndrome[24]	**Prof. Z. Pejsak & Dr K. Podgórska** National Veterinary Research Institute, Pulawy, Poland. **Dr K. Tian** Veterinary Diagnostic Laboratory, China Animal Disease Control Center, Beijing, China (People's Rep. of).
3.9.7. Influenza A viruses of swine[25]	**Prof. I. Brown** APHA Weybridge, New Haw, Addlestone, Surrey, Weybridge, UK.
3.9.8. Swine vesicular disease	**Dr D. King** The Pirbright Institute, Ash Road, Woking, Surrey, UK. **Dr E. Brocchi,** Istituto Zooprofilattico Sperimentale della e dell'Emilia Romagna (IZSLER), Brescia, Italy.
3.9.9. Teschovirus encephalomyelitis	**Mr N. Knowles** The Pirbright Institute, Ash Road, Woking, Surrey, UK.

23 This chapter was updated by consensus of the WOAH *ad hoc* Group on Classical Swine Fever (vaccine section) and of all WOAH Reference Laboratories for classical swine fever (diagnostic section).

24 This chapter was updated with help from: Nicolas Ruggli (The Institute of Virology and Immunology, Mittelhäusern, Switzerland); Tomasz Stadejek (Warsaw University of Life Sciences, Warsaw, Poland).

25 This chapter was updated by consensus of all WOAH Reference Laboratories for swine influenza.

3.9.10. Transmissible gastroenteritis	**Dr L.J. Saif** The Ohio State Universtiy, Ohio Agricultural Research and Development Center, Food Animal Health Research Program, Wooster, Ohio, USA.
3.10.1. Bunyaviral diseases of animals (excluding Rift Valley fever and Crimean–Congo haemorrhagic fever)	**Dr B.A. Lubisi** Onderstepoort Veterinary Institute, Agricultural Research Council, Onderstepoort, South Africa. **Dr M. Beer & K. Wernike** Institute of Diagnostic Virology, Friedrich-Loeffler-Institut, Federal Research Institute for Animal Health, Insel Riems, Germany. **Dr M. Baron (retired)** UK. **Dr P. Kirkland** Elizabeth Macarthur Agriculture Institute (EMAI), Virology Laboratory, Menangle, Camden, New South Wales, Australia.
3.10.2. Cryptosporidiosis	**Dr R. Chalmers** Cryptosporidium Reference Unit, Public Health Wales Microbiology, Singleton Hospital, Swansea, UK.
3.10.3. Cysticercosis	**Prof. P. Dorny & Prof. S. Gabriël** Department of Veterinary Public Health and Food Safety, Faculty of Veterinary Medicine, Ghent University, Merelbeke, Belgium
3.10.4. Infection with Campylobacter jejuni *and* C. coli	**Prof. J.A. Wagenaar & Dr L. van der Graaf-van Bloois** Department of Infectious Diseases and Immunology, Faculty of Veterinary Medicine, Utrecht University, Utrecht, The Netherlands.
3.10.5. Listeria monocytogenes[26]	**Dr A. Leclercq** Institut Pasteur, CNR & CCOMS Listeria, Unité de Biologie des Infections, Paris, France.
3.10.6. Mange	**Dr J.L. Schlater & Dr J.W. Mertins** Parasitology and Clinical Pathology Section, Pathobiology Laboratory, National Veterinary Services Laboratories, USDA, APHIS, VS, Ames, Iowa, USA.
3.10.7. Salmonellosis[27]	**Dr R. Davies (retired)** UK.
3.10.8. Toxoplasmosis	**Dr J.P. Dubey** Animal Parasitic Diseases Laboratory, USDA, Agricultural Research Service, Beltsville, Maryland, USA.

26 This chapter was updated with help from: Dr R. Rathbone (AOAC, USA); Dr G. Riegler (AOAC, USA); Dr K. Jinneman (FDA, USA); Dr Y. Chen (FDA, USA); Dr T. Hammack (FDA, USA); Dr S. Granier (Anses Maisons-Alfort, France); Dr R. Danguy-des-Deserts (Laboratoire départementale de développement et d'analyses, France); Dr A. Oevermann (University of Bern, Switzerland).

27 This chapter was updated by consensus of all WOAH Reference Laboratories for salmonellosis.

3.10.9. Verocytotoxigenic Escherichia coli

Dr F.A. Clifton-Hadley
APHA Weybridge, New Haw, Addlestone, Surrey, UK.

3.10.10. Zoonoses transmissible from non-human primates

Dr S. Edwards (retired)
UK.

Dr T. Brooks
Rare & Imported Pathogens Laboratory, Public Health England, Porton Down, Salisbury, UK

PART 1

GENERAL STANDARDS

SECTION 1.1.

INTRODUCTORY CHAPTERS

CHAPTER 1.1.1.

MANAGEMENT OF VETERINARY DIAGNOSTIC LABORATORIES

INTRODUCTION

Reliable laboratory services can be delivered only by specialised facilities that are appropriately constructed and managed to provide the operating environment where the complex interaction of qualified staff, infrastructure and scientific methods can be coordinated to deliver specialised outputs consistently and safely. This chapter describes components of governance and management of veterinary laboratories that are necessary for the effective delivery of a diagnostic service, highlighting the critical elements that should be established as minimum requirements. Subsequent chapters set more specific standards for managing biological risks associated with laboratory facilities and for the range of aspects to be addressed to ensure confidence in laboratory test results.

The essential prerequisite for effective laboratory management is a clear understanding of the outputs required by the managing jurisdiction. National governments should support laboratory systems by developing a national laboratory policy based on the definition of the categories of laboratory test results required for effective implementation of the national animal health policy, including tests in support of international trade. Such clarity regarding national animal health requirements for laboratory services will guide the formation of national strategic planning for the delivery of these services. A clear statement of expectations of the laboratory service will guide governance and resourcing arrangements.

Further to these considerations, this chapter specifies components of diagnostic service management and delivery including the key support services that are considered essential. In addition to making provision for the scientific and technical aspects of the laboratory activities, the laboratory management system must address biorisk management and quality assurance. Laboratory management must also understand and meet the national and international regulatory requirements governing diagnostic laboratory operations. The outputs from a veterinary laboratory must be based on sound science, and mechanisms must be in place to prevent corrupt practices and inappropriate political influences.

A. GENERAL CONSIDERATIONS

1. Introduction

Laboratories fulfil an essential role in the delivery of veterinary services. Without the data and information supplied by veterinary laboratories, animal disease detection, control and prevention would be significantly weakened (Edwards & Jeggo, 2012). Veterinary laboratories are also a valuable resource to increase national laboratory capacity during major human health events such as pandemics.

Chapter 1.1.6 *Validation of diagnostic assays for infectious diseases of terrestrial animals* lists the usual purposes for which laboratory testing is conducted, which include demonstration of freedom from infection in defined animal populations, certification of freedom from infection in individual animals or products for trade/movement purposes,

contributions to the elimination of infection from defined populations, confirmation of diagnosis of suspect or clinical cases, estimation of prevalence of infection or exposure to facilitate risk analysis, and determination of the immune status of individual animals or populations.

These roles can be provided by governments (public sector laboratories), by industry (private sector laboratories), by universities (university laboratories) or by other organisations. Combinations of such providers in a complex matrix of services create challenges in the management and expectations of service delivery.

The governance of public sector veterinary laboratories will vary from country to country according to their public sector processes. This chapter sets out the general principles of governance and management for all types of veterinary laboratories that should ensure that Veterinary Services have access to reliable, trustworthy laboratory services, data and advice. The governance framework should ensure strong and effective delivery of services in a manner that is politically accountable, transparent, ethical, forward-looking and fair to staff and customers.

2. Accountability and oversight

A veterinary laboratory is held accountable for a range of issues apart from the delivery of basic diagnostic services. These may include health and safety, biosecurity, animal welfare and ethics, environmental contamination, genetic manipulations and quality assurance. It is essential that processes are established for the management and reporting of these issues and that individual staff are held accountable for their formally delegated responsibilities. As part of the process, it is critical to recognise and manage the resource implications, as failure to deliver to these accountabilities can bring the laboratory service into disrepute, detracting from the credibility of national animal health services.

There must be a clearly communicated and effective process by which the laboratory management is assessed and held accountable for delivery of all aspects of service delivery and accountability. This may be through a formally constituted governing body or through line management by the veterinary services or other qualified arm of government. Where a governing board is appointed, an independent chairman should be selected who understands both the political and the scientific environments in which the laboratory operates. The governing board should advise the laboratory director[1] on how to meet the expectations of the customers and owners of the laboratory, but should also represent the laboratory's interests by ensuring that these customers and owners have realistic expectations of the laboratory's capability and capacity, both in normal day-to-day operation and during outbreaks.

Whatever the governance structure, those responsible must ensure that the managers and scientific staff of the laboratory can operate in a scientifically sound environment and are free from inappropriate political influences. This includes the publication of the results of scientific research. A zero-tolerance approach to corruption at all levels must be in place.

A laboratory should have a medium-term strategic plan and a more detailed business plan for the year ahead, including financial and resource management. The director of the laboratory is ultimately responsible for ensuring the management of the laboratory according to these plans and obtaining appropriate governance agreement. The laboratory should also prepare an annual report for approval through the established oversight processes.

The governing body must not become involved with the operational management of the laboratory, which must remain firmly in the hands of the director and the management team.

It is important to review regularly the overall laboratory objectives and agreed deliverables with government to ensure transparency in meeting of expectations. Staff should be kept informed on such deliverables, understand priorities and not feel unduly threatened by the need to ensure financial security for the laboratory. There may be competing pressures with regards to the activities that need to be undertaken, and the director should continually provide leadership and guidance to staff on these issues.

3. Executive management

It is essential that operational activities in the laboratory are conducted under the authority of a single individual who is given an appropriate title, e.g. director or chief executive. The director (or equivalent) should be fully

1 The term "director" is used generically in this chapter to refer to the senior responsible person in the laboratory. Local terminology may vary, and this role is further discussed in Section A.3 of this chapter.

accountable for the delivery of outputs from the laboratory and for the deployment of resources within the institution. As the core role of the laboratory is to participate in the diagnosis of animal disease and disease control programmes, the director should ideally be a qualified veterinarian and also have personal experience of working in a laboratory environment. Where the director does not have a veterinary qualification, a senior deputy should be appointed in the role of veterinary director. The key attributes of the director are to have an understanding of the operating environment of laboratory work, to be fully aware of the end-user requirements so that the outputs are relevant, trustworthy and timely and to demonstrate leadership qualities that will motivate the laboratory staff to deliver their best and to the required quality standard, both during normal operations and in outbreaks.

The director should be supported by a senior management team whose members will lead specific aspects of the work of the laboratory. The size of this team, and the scope of their individual responsibilities, will depend on the size of the laboratory, but it will typically involve leaders of different scientific disciplines (e.g. pathology, bacteriology, virology) as well as business leaders with expertise in human resources (HR), finance, procurement, engineering, information technology (IT) and communication. At least one of the senior team should be designated deputy director; the deputy will work closely with and in support of the director and fulfil the director's responsibilities in his or her absence.

4. Infrastructure

Laboratories are highly specialised facilities with very particular requirements in terms of buildings, services and operational environments. Although some smaller laboratories can operate within an adapted general-purpose building, it is highly recommended that veterinary laboratories are housed in purpose-built units, designed with considerable input from scientific staff, along with architects, environmental experts, safety advisers and others in the design team. The structure and functions of the laboratory must comply with all relevant national regulations and international standards, such as for biocontainment, biosafety and environmental impact. Local issues must also be taken into account, such as the likelihood of extreme conditions (high or low temperatures, earthquakes, hurricanes, floods) and the reliability of water and electricity supplies.

National authorities must recognise that laboratories, whilst very expensive to build, are equally expensive to operate and maintain. It is absolutely essential that an adequate, ongoing budget be allocated for annual operating costs (see section on finance below). Factors to support include the IT data support requirements (including future-proofing), utility costs and waste management. Likewise, as technologies and legislative requirements change, budgetary commitments to equipment and laboratory upgrades should be planned well in advance.

5. Human resources

A veterinary laboratory, like any organisation employing staff, must have a clear, transparent HR policy that is seen to treat all individuals fairly. Appropriate procedures should be in place to determine remuneration, performance management, appraisal and promotion, leading to incentivisation and reduced risk of departure of well-trained staff. A robust mechanism for addressing poor performance is also essential; it should provide clear and fair procedures for dismissal, in extreme circumstances. Veterinary laboratories employ an unusually high proportion of specialised staff, and this can cause difficulties where work patterns change as new technologies are introduced. HR policies should include training and retraining programmes to ensure that all staff are developed to their full potential and contribute to a flexible work force. It is prudent to encourage staff, particularly new entrants, to move around different sections of the laboratory as part of their development. This breadth of experience ensures increased resilience in outbreaks, and also builds tolerance, as staff develop an appreciation of the challenges of different disciplines – and they also make better leaders.

6. Compliance

6.1. Health and safety

Veterinary laboratories are hazardous environments. Most hazards fall into three main categories: biological, chemical and physical. There are biological risks from handling dangerous pathogens, including infectious zoonotic agents (i.e. those that may infect humans), recombinant forms of infectious agents, viral vectors, biologicals introduced into experimental animals and allergens from handling animals. Hazardous chemicals can result in exposure during use, if misused or mishandled, or through inappropriate storage. Appropriate personal protective equipment must be used to protect personnel from exposure to toxic, carcinogenic or otherwise hazardous chemicals. Risks from physical hazards can include ergonomic issues associated with manual tasks, handling sharps, poor housekeeping, ionising

radiation, ultraviolet radiation, fire, high-pressure steam, liquid nitrogen, solid CO_2 vessels and animals (bites, kicks and other trauma to staff). Health and safety (H&S) must comply with the applicable national H&S legislation where such exists and be managed in a transparent and documented manner. The laboratory must have policies and procedures in place to assess all risks to staff (and visitors) and to mitigate those risks to acceptable levels. Risk assessments should be performed by the individuals most familiar with the specific characteristics of the pathogens being considered for use, the equipment and procedures to be employed, animal models that may be used and the containment equipment and facilities available.

It is the responsibility of the laboratory senior management to ensure the development and adoption of H&S policies and procedures. Training of new and existing personnel is key to avoiding accidents. Appointment of an H&S professional should be a serious consideration for larger laboratories, and this should be supported by an appropriate, dedicated H&S budget. The role of the H&S professional must be clearly defined and documented, and all personnel (including visitors) should understand that the presence of an H&S professional does not mean that they are any less responsible for carrying out their work in a safe and responsible manner, in compliance with agreed protocols. The H&S professional must have the full support of laboratory senior management. Personnel should be advised of special hazards, required to read and have easy access to the laboratory safety or operations manual, follow standard practices and procedures and participate in regular training.

A H&S committee should be established consisting of representatives from both staff and management of the laboratory. A requirement for such committee structures and operations is usually included in national legislation, and the laboratory managers must be fully conversant with these defined processes, including the appointment of H&S representatives, actions and reporting procedures for all H&S incidents, H&S training requirements and the minimum laboratory infrastructures and processes to meet these requirements. For larger facilities that may also carry out additional activities, including research, a biological safety officer, a chemical safety officer and a more formal institutional biosafety committee, with external representation, may also be of benefit in assessing and managing additional biosafety risks. Such a committee should also apply oversight and guidance on dual use research of concern[2].

6.2. Biosafety and biosecurity

In addition to health and safety issues, veterinary laboratories have a responsibility to contain pathogens and to prevent unauthorised access to reduce the risk of their accidental or deliberate release that might threaten neighbouring human or animal populations, or the environment. Standards on biorisk management are given in Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities* and in the WHO[3] Laboratory Biosafety Manual (WHO, 2020). All veterinary laboratories should comply with the relevant standards in these documents and also adhere to national standards and regulations. In many countries there is a national compliance monitoring authority for biosecurity or biocontainment. This authority will inspect the laboratory on a regular basis. The laboratory managers must understand the regulations and ensure that sufficient resources are available to ensure compliance. For laboratories undertaking investigations of new and emerging diseases or pathogens, the potential zoonotic risk to staff and the general population should also be subject to a risk assessment and appropriate mitigation measures put in place where potential risks are identified. Brass *et al.* 2017 provide a useful summary of methodologies used to assess risks posed by novel pathogens, as well as covering the fundamentals of laboratory biosafety and biosecurity.

Whilst minimum legal requirements exist, individual laboratories should examine their processes and procedures to determine where elements of biosecurity risk may arise and how best these should be managed on a local basis. A biorisk manual that contains standard operating procedures (SOPs) for all activities should be maintained, with version control. Such SOPs should highlight biosecurity controls, training should be provided, and it is recommended that local procedures are put in place to manage non-compliance. This is a matter of good laboratory practice, regardless of the legislative background.

2 WOAH Guidelines for responsible conduct in veterinary research: https://www.woah.org/fileadmin/Home/eng/Our_scientific_expertise/docs/pdf/BTR/A_GUIDELINES_VETERINARY_RESEARCH.pdf

3 WHO: World Health Organization

Laboratory biorisk management should specifically recognise the potential for bioterrorist threats including the concept of the insider threat (e.g. the bioterrorist threat posed by a staff member or visiting scientist). When working with high consequence pathogens, a process should be developed by which this threat can be managed. Physical security measures and an annual staff threat appraisal would be a minimum requirement in such circumstances and security screening of staff may also be considered. In addition, measures must be in place to control access by visiting scientists and to ensure their supervision when working with this class of pathogens.

Where required by regulation or organisational policy, written confidentiality agreements should be in place for appropriate personnel including staff, visiting scientists, contractors and others, to prevent any confidential information being released inappropriately.

6.3. Animal welfare

Veterinary laboratories must ensure their activities comply with animal welfare standards (Section 7 of the *Terrestrial Animal Health Code*, particularly Chapter 7.8 *Use of animals in research and education*). It is also essential to understand fully the national legislation governing the ethical use of animals and put in place processes to ensure compliance. An institutional animal ethics committee, with external representation, is recommended.

6.4. Gene regulation

Many laboratories now use modified genes or gene products in their activities. Compliance with national regulations governing their use must be ensured including establishment of systems in the laboratory to monitor and ensure such compliance. International obligations concerning ethical behaviours in genetic manipulation in the context of Dual Use Research of Concern (DURC)[4] also apply (WOAH, 2019). Particular attention should be given to experiments that might fall into the category or "Gain of Function", where the host specificity or virulence of a pathogen might be altered.

6.5. Environment

Laboratory waste may create concerns of environmental pollution. The risk of environmental damage from carcass disposal and disposal of other biological material is an issue that requires specific attention. Understanding and managing, as far as possible, any potential negative impacts of the laboratory on the surrounding environment is important and may be subject to national and local regulations. Certification of compliance with standard ISO[5] 14001:2015 *Environmental Management Systems* (ISO, 2015) should be a target for laboratory managers. The laboratory should not be established in an inappropriate environment such as close to other facilities that may impact on the safety of the laboratory.

B. SCIENTIFIC SERVICES

1. Diagnostic service delivery

The national Veterinary Services must be very clear in specifying the purposes for which laboratory capability is required, and hence the test methods and technologies to be supported. The defined purposes will include the list of diseases or infectious agent groups in scope, the nature of the government programmes to be supported in terms of the purposes of testing outlined in chapter 1.1.6, the likely scheduling and volume of submissions, and the required turnaround time for test reports. The cost implications must be identified and agreed. These discussions should be recorded in a service level agreement or similar documentation.

A key component of the delivery of scientific services is the routine monitoring, calibration and maintenance of scientific equipment. This is a real challenge in terms of both the resources to maintain the process and the availability of trained engineers and calibration equipment. Managing these processes should be a priority for

4 DURC: https://www.who.int/csr/durc/en/
5 ISO: International Organization for Standardization

resource allocation as test results generated on unmaintained and uncalibrated equipment cannot be trusted to be accurate.

Provision should also be made for the laboratory services that will be required in a disease emergency. The laboratory maximum (surge) capacity for processing samples should be defined as well as a plan for scale-up of operations. This may include a diversion of resources from lower priority tasks. Capacity may be disease-specific and test turnaround times are also an important element in this specification.

All countries should support WOAH designated Reference Centres through submission of specimens, isolates of infectious agents and other information of potential regional or international significance. It is only through receipt of such submissions that the Reference Centres can fulfil their WOAH mandated role on behalf of the international community. Involvement with the designated Reference Centres is necessary for international public good.

In turn, national veterinary laboratories with special expertise in particular areas may seek recognition from international bodies such as WOAH, FAO[6] or WHO as reference laboratories or collaborating centres. This is encouraged, as it facilitates the harmonisation of laboratory procedures worldwide, and strongly supports the work of WOAH and other international organisations. Funding for reference laboratory status needs to be allocated from national sources, and this should be part of the national planning with the Veterinary Services.

Many veterinary laboratories carry out work for a range of different customers. As well as meeting the needs of Veterinary Services, the laboratory may conduct contract work for national or international parties, provide diagnostic and surveillance procedures for private veterinarians, veterinary organisations or livestock industries, test food or environmental samples for food safety or other public health reasons, perform regulatory testing of veterinary medicinal products, and carry out contract testing for the private sector, e.g. for pharmaceutical companies. It is the responsibility of the laboratory director and management team to ensure that a balanced approach is taken in the allocation of resources in order to deliver this complex array of services. There should be clear recognition of priorities to facilitate dealing with unexpected events such as disease emergencies.

In some countries, laboratory services are delivered through a number of laboratories, rather than through a single laboratory. In such cases, it is essential that the laboratories form a network, sharing best practice and information on testing, such that the Competent Authority has assurance that the same result is obtained, wherever testing is performed.

2. Quality assurance

Veterinary laboratories must be managed under a quality assurance system as specified in Chapter 1.1.5 *Quality management in veterinary testing laboratories* and should preferably be accredited to an international standard such as ISO/IEC 17025 *General requirements for the competence of testing and calibration laboratories* (ISO, 2017). The laboratory should ensure that all of its procedures, not just those concerning the laboratory bench but also those for supporting documentation and computer records, are robust, reliable and repeatable.

The quality standards require that diagnostic tests used in the laboratory should be validated as fit for purpose. The international standard for validation of diagnostic tests is established by WOAH and is set out in chapter 1.1.6. Validation is not a once-for-all-time procedure but requires continual monitoring and refinement as the test is used. Laboratories should strive at all times to use tests that have reached at least stage 3 on the WOAH validation pathway (chapter 1.1.6) and to continue refining the validation data as explained in the text.

3. Research

Laboratories are likely to engage in research, such as development or adoption of new tests or test methods, or pathogenesis or epidemiological studies of infections important in the particular country. It is essential to manage effectively the balance between research and diagnostic service delivery and the potential for competition for resources, including staff time. Many laboratories undertake research aimed at disease awareness, preparedness and mitigation, and to inform policy in “peacetime”, with the research space configured and scientists trained and deployed to disease investigation and surge capacity diagnostic functions during outbreaks. Furthermore, such capability can provide for investigation of new and emerging diseases, or variants of known disease. Publication of

6 FAO: Food and Agriculture Organization of the United Nations

emerging disease threats, novel methods of detection and sharing of protocols with Reference Laboratories is encouraged.

4. Information and data for disease surveillance

Diagnostic laboratories may play a critical role in providing laboratory information and data to support routine disease surveillance activities and hence the claim of disease status in the country, which is essential to maintaining domestic and international trade. Apart from using fit-for-purpose surveillance tests as detailed in the relevant disease and quality management chapters of this *Terrestrial Manual*, laboratories should endeavour to ensure the compatibility of relevant information and data with that used in their central or national animal health systems if available or applicable.

C. SUPPORT SERVICES

1. Internal governance: policies and procedures

To ensure adequate standards of laboratory management across the spectrum of roles and responsibilities as identified in this chapter the responsible authority for the laboratory must ensure that laboratory management has adequate arrangements in place to deliver the required outcomes. These arrangements will include clearly defined policies and procedures supported by a management structure that is adequately resourced for implementation, audit and review. In many areas of activity, national legislation may provide the overarching standards to which laboratories must work and it is essential that compliance is seen to be mandatory, for the welfare of staff, the protection of the environment and the reputation of the laboratory.

Laboratory management should agree and document its policies for all aspects of operational activities. The processes by which such policies are implemented should also be documented in the form of clear procedures that are communicated to all staff who are involved in the particular activity. This approach has been introduced in some laboratories through the development of a quality assurance system, and is also applicable to other aspects of laboratory activity. The responsibilities of designated staff for oversight and implementation of policies and procedures should be included in the documentation and communicated clearly to all staff on the laboratory site.

2. Information management

Modern laboratories are increasingly dependent on computerised systems to manage their data. This can include an all-encompassing laboratory information management system (LIMS), bespoke systems for controlling individual laboratory equipment, and sophisticated analytical systems for use by specialised information scientists in disciplines such as molecular biology, informatics, epidemiology, risk analysis and statistics. A system that monitors location and quantities of high consequence pathogens is also common in high containment laboratories. There will also be office support systems for word processing, finance, HR and bibliographic databases. Systems for internal and external communications such as websites and email services will be needed. As with other elements of the laboratory's activities, it is essential that the computer systems are managed by competent professionals and that the scientific staff are consulted in specifying the services they require. Measures must be in place to protect the integrity of the data, for archiving and retrieval, and for privacy protection of personal or sensitive items. It is important that the laboratory clearly determines its needs and procures the necessary resources, either through a service contract with an IT support company or through the direct employment of IT professionals, so as to provide adequate support in this essential area.

3. Finance

The budget is an integral part of the annual laboratory business plan and will set a basis for negotiation with customers and funders. The director should be personally accountable for delivering the work programme of the laboratory within budget, while individual managers of projects or activities should be set delegated delivery and financial targets. For any but the smallest of laboratories, the director should be supported in this area by one or more finance professionals.

Laboratory management should identify all costs and their allocation to the appropriate area of activity, so that the total cost of delivering any particular service can be identified. The operating costs should include directly attributable items (such as reagents and equipment), staff time per procedure, administration (booking in samples,

generating reports), capital equipment (the cost of which may need to be spread across multiple activities or projects) and an appropriate proportion of overhead costs (covering such items as management, buildings, utilities, IT services, safety and quality procedures, and storage and archiving of samples and records).

Cost control is an essential part of laboratory management. Continual efforts should be made to improve efficiency without compromising on quality. It is to be expected that customers will seek to minimise the costs to them of the services received; however; it is also important that the Veterinary Services or other laboratory customers recognise the complexity of the expenses in running a laboratory.

For many laboratories revenue generation through the sale of services and products is an important component of their finances. There may be political or regulatory constraints that determine whether such activities can make a profit, break even or be subsidised from the government allocated funds, but in all cases where the laboratory recovers costs from submitters, the laboratory should have a transparent pricing policy.

An important aspect of financial management is procurement of equipment, laboratory supplies and services. It is likely that there will be government regulations with which the actual procurement processes must comply. However it is important that the scientific staff of the laboratory should prepare detailed specifications of their requirements, whether for reagent supplies, equipment, or external provision of services. If the specification is well prepared, then the procurement process should be able to secure appropriate supplies of the product at the required quality. Clear rules must be in place to prevent undue pressure or bribery being applied to procurement officers by suppliers. This risk must be monitored closely by the senior management of the laboratory and, if necessary, by the governing body.

4. Engineering and maintenance

A modern veterinary laboratory requires substantial and adequate engineering maintenance and support. It is possible to outsource many of these maintenance requirements, but in many cases an in-house capability may better serve the need. Familiarity of engineering staff with the biological impacts and risks associated with the systems is also important to ensure maintenance and repairs can be conducted safely. Most laboratories have site-specific needs and requirements that are best met with a reasonable complement of engineering and trade skills on site, with staff who are familiar with local needs and issues. A robust reliability programme helps to identify critical points of failure and ensure planned, preventive maintenance of these elements. Sufficient stocks of spare parts and supply lines should also be in place, supported by a stock management system, to ensure continuity. Maintenance schedules affecting laboratories should be carefully programmed in consultation with laboratory users to ensure continuity of operations as far as practicable. Laboratory management should regularly review how best to supply these support services.

5. Communications

Good communications that result in transparency of decision making and operations are vital to the success of a laboratory enterprise. This includes internal communications within the laboratory, ensuring that all staff are aware of the current priorities and how these impact on their work individually, as well as the wider activities of the laboratory and how their efforts contribute to the whole. It is essential that senior management is visible and has a system for communicating with staff throughout the laboratory and that this process genuinely works both ways. Senior managers must make efforts to be aware of the concerns and aspirations of their staff.

Externally, the director and management team must be effective advocates for the laboratory and represent it in meetings with Veterinary Services and other government officials, with scientists from other institutions, nationally and abroad, or with the wider public, including the media. It follows that the director and senior managers should be trained to interact with the media. This is a major priority particularly during a disease emergency, when effective communications with laboratory stakeholders is essential.

The key outputs from a veterinary laboratory are the scientific results and interpretation stemming from its analytical and investigational activities. These must be communicated to the customers or end-users in a clear, unambiguous and meaningful manner. Laboratory reports should include, where appropriate, indications of the level of uncertainty in the results, whether further results are still pending, and how to raise queries or clarifications or request further work. For their part, customers should be encouraged to provide as much additional relevant information as possible, when submitting samples, as this can greatly aid laboratory investigation and the interpretation of results.

A public information policy and procedures should provide a mechanism for individuals and outside bodies to ask about specific activities in the laboratory. Communications support staff should be involved in ensuring that the laboratory's customers are kept informed about the work of the laboratory, its successes and any constraints on future work. Laboratories may provide an internet website or other IT-based strategies to assist with such communications. The management team should also ensure that procedures are in place to ensure compliance with obligatory reporting and notification requirements.

Scientific staff should be encouraged and supported to attend conferences and present papers, while the production of a steady stream of good-quality written papers in refereed journals is vital to the success of a laboratory institution. Importantly, this does not apply only to the research scientists; those working in diagnostic and surveillance work can also play an important role.

D. CONCLUSIONS

Good governance and management of a veterinary diagnostic laboratory are essential for the safe, sustainable and effective delivery of a diagnostic service. This chapter identifies the range of issues to be addressed if laboratories are to meet international standards. Many aspects of the delivery of laboratory services are now highly regulated by national authorities, and laboratory managers must be familiar with these regulations and have compliance processes in place. Key elements of staff safety, biocontainment, biosecurity, quality assurance, animal welfare and environmental management are vital components of operating such facilities. The governance and management of these aspects are as important as the delivery of the actual diagnostic service.

A well managed laboratory will further ensure that the general provisions specified in the remaining chapters of Part 1 of this *Terrestrial Manual* are met as well as the specific standards for the diagnostic testing for specific disease agents as outlined in Part 2. A key component in providing customer assurance is conforming with the WOAH quality standard (chapter 1.1.5) supported by accreditation to quality standards such as ISO 17025. Accreditation is an important achievement of which laboratory staff can be proud, and implies that underlying compliance issues have been addressed.

Fundamental to the effective delivery of diagnostic services is the operation and maintenance of the facility and the scientific equipment. Allocation of adequate ongoing resources to this area is vital.

A successful veterinary diagnostic laboratory will have a highly trained, motivated workforce, with respect and support given to all individuals including both the frontline scientific staff and the important support teams providing vital services in areas such as finance, HR, safety, quality, procurement, engineering, IT and communications.

The achievement of all the above, and delivery of a respected and reliable service, requires a management system with checks and balances and effective review. This will include mechanisms to ensure political accountability, transparency, responsiveness, and coherent planning to ensure sustainability. A structure that includes an oversight process is strongly advocated to assist both financial management and strategic approaches to the delivery of all aspects of the laboratory's activities.

CHAPTER 1.1.2.

COLLECTION, SUBMISSION AND STORAGE OF DIAGNOSTIC SPECIMENS

INTRODUCTION

Laboratory investigation of animal disease is critically dependent on the quality and appropriateness of the specimens collected for analysis. This chapter sets out the general standards involved in specimen collection, submission, and storage. The individual disease chapters in this Terrestrial Manual provide specific information on appropriate specimens needed to test for particular pathogens or toxins. Sampling may be from individual animals, from animal populations, or from the environment for a variety of purposes, such as disease diagnosis, disease surveillance, health certification, and monitoring of treatment or vaccination responses. To provide scientifically and statistically valid results the specimens collected must be appropriate for the intended purpose, and adequate in quality, volume, and number for the proposed testing. Additionally, the animals and tissues sampled must be appropriately representative of the condition being investigated.

Specimens must be collected using appropriate biosafety and containment measures in order to prevent contamination of the environment, animal handlers, and individuals doing the sampling as well as to prevent cross-contamination of the specimens themselves. Care should additionally be taken to avoid undue stress or injury to the animal and physical danger to those handling the animal. Biological materials should be packaged to rigorously control for leakage, and then labelled with strict adherence to the applicable regulations guiding their transport as outlined in Chapter 1.1.3 Transport of biological materials.

A. COLLECTION OF SAMPLES

1. General considerations

Careful consideration must be given to the collection, containment, and storage of the specimens, including biosafety measures that must be in place to prevent contamination of the environment or exposure of other animals and humans to potentially infectious materials (see Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*). For information on transport of specimens see Chapter 1.1.3 *Transport of biological materials.*

The reliability of the diagnostic testing is critically dependent on the specimen(s) being appropriate, of high quality, and representative of the disease process being investigated. Prior to sampling, consideration must be given to the type of specimen(s) needed including the purpose of the testing and the test technologies to be used. The volume or quantity of specimen must be sufficient to perform initial testing, to perform any subsequent confirmatory testing and to provide sufficient residual specimen for referral or archival purposes.

The purposes of testing will be aligned with the purposes for which tests are validated, as listed in Chapter 1.1.6 *Validation of diagnostic assays for infectious diseases of terrestrial animals*, namely:

i) Demonstration of freedom from infection in a defined population.

ii) Certification of freedom from infection or presence of the agent in individual animals or their products for trade/movement purposes.

iii) Eradication of disease or elimination of infection from defined populations.

iv) Confirmatory diagnosis of suspect or clinical cases.

v) Estimation of prevalence of infection or exposure to facilitate risk analysis.

vi) Determination of immune status of individual animals or populations (post-vaccination).

Epidemiologically appropriate sampling plans should be developed prior to collection of specimens, as described in Section B and Appendix 1.1.2.1. These will specify the number of animals or other sampling units to be sampled.

Specimens must be collected according to a sound knowledge of the epidemiology and pathogenesis of the disease under investigation, or the disease syndrome to be diagnosed. This will lead to the sampling of tissues or fluids most likely to contain the infectious agent or evidence of the infection. Considerations will include the tissue predilection(s) or target organ, the duration and site of infection in each tissue type and the duration and route of shedding, or the time frame in which evidence of past infection, such as an antibody response, can be detected reliably by the tests to be deployed. These considerations will also indicate the method(s) of collection to be used. In many herd or flock-based disease investigations it is beneficial to collect specimens from a healthy cohort for comparative epidemiological or baseline testing (e.g. case-control and cohort approaches for diagnostic testing) and for validation purposes.

Where chemical euthanasia or anaesthesia is required for animal restraint, the impact of the chemical on the test result (e.g. toxicology testing) must be considered. Some laboratory tests are not compatible with specific blood anticoagulants and tissue preservatives, such as heparin, formalin, dry ice (exposure of the test sample to elevated levels of CO_2), or even freezing. While it is critical to collect specimens as aseptically as possible, equal care must be taken to avoid contamination with detergents and antiseptic treatments used to clean the collection site on the animal, as these agents may interfere with the laboratory test procedures. Procedures requiring tissue culture of pathogens, as well as many molecular-based tests, can be negatively affected by chemicals or detergents commonly used in the manufacture or preparation of collection tools (e.g. chemicals used in manufacture of some types of swabs and detergents used in cleaning glassware).

Specific information on diagnostic test methodologies and the recommended specimens, preservatives, and specimen handling procedures can be found in the individual *Terrestrial Manual* disease chapters or through direct consultation with the laboratory that will be performing the required testing. Procedures for collection and submission of specimens are available from most diagnostic laboratories, including national and international authorities, where the information is frequently accessible via the specific laboratory's web page. The WOAH web page provides contact information for all WOAH reference laboratories[1].

It is critical not only to collect the most diagnostically-appropriate specimens, but to also inform the laboratory of the associated disease epidemiology in order for the laboratory scientists to assign the most appropriate tests or panels of tests. Epidemiological information to be submitted with specimens is outlined in Section C of this chapter.

Where investigating diseases of unknown cause multiple different specimens that represent the different stages of the disease progression in an animal or the population of animals (e.g. the pre-clinical, early clinical, active clinical, chronically affected and convalescent phases) should be collected. Epidemiological considerations for sampling are particularly critical for diagnosing population-related diseases, as would occur with beehives, flocks, and herds. Epidemiological principles used for sampling are further introduced in Section B of this chapter.

Specimens can be collected ante-mortem or post-mortem. Specific considerations regarding different specimen types are as outlined below.

2. Blood

Whole blood samples may be collected for haematology, clinical chemistry, toxicology, direct examination for bacteria or parasites, PCR testing, immunological testing, or for culture for bacteria or viruses. Dependent on testing needs, whole blood, blood cells, and/or plasma samples can be obtained from whole blood collected into appropriate anticoagulants. In selecting the anticoagulant to be used the collector must be aware of the laboratory tests, including PCR-based diagnostics, clinical chemistry, and toxicology, which may be negatively affected by the presence of specific anticoagulants or preservatives. Specific disease chapters in this *Terrestrial Manual* provide guidance for individual tests and sample requirements. To be effective anticoagulants require that the collected

1 https://www.woah.org/en/what-we-offer/expertise-network/reference-laboratories/#ui-id-3

blood be thoroughly mixed with the chosen anticoagulant during or immediately following its sampling from the animal.

To obtain serum, whole blood is collected without anticoagulants and the clot is allowed to contract at ambient temperature protected from extremes of heat and cold for periods that may range from a few hours to overnight. Clear serum can be decanted or collected by pipette following physical removal of the clot, ideally following gentle centrifugation to separate cell components from the serum. In the absence of a centrifuge, separation of the clot can be facilitated by tilting the freshly collected blood tube at an approximate 45 degree angle until the clot has retracted, "ringing" the clot with a sterile rod or pipette to separate the clot from the tube surface, and then removing the clot with forceps. The results of serological testing can be compromised by the quality of the sample. Bacterial contamination and red blood cell debris in serum samples can produce false positive reactions in agglutination-type assays. Serological assays can be negatively impacted by haemolysis in the serum sample. Microbial contamination and haemolysis are significant concerns especially when obtaining blood and serum samples from post-mortem animals. Frequent causes of haemolysed serum and plasma include exposure to excessive temperatures or time delays prior to separating sera from the red blood cells, blood collection using a needle of too small gauge, or failure to remove the needle when transferring the blood sample from the collection syringe.

Whole blood should be collected aseptically, typically by venipuncture of the live animal. Depending on the animal and sampling situation jugular, caudal, brachial, cephalic, mammary veins or the vena cava may be used. Specific techniques for sampling small laboratory animals have been reviewed (Anon, 1993; Hem *et al.,* 1998). Care should be taken to collect and dispense blood samples as gently as possible to prevent damage to red blood cells, which causes haemolysis. Blood and sera are typically shipped and stored cool (or frozen in the case of sera) in non-breakable vials, tubes, or bottles; however for some laboratory tests that require viable peripheral blood mononuclear cells, the blood must be packaged, transported and stored so as to prevent exposure to temperature extremes. For some tests, aliquots of specimens can be dried onto a piece of untreated, or specifically-treated commercial filter paper designed for stabilised sample transport and storage.

3. Faeces

Faeces can be collected freshly voided or preferably directly from the rectum/cloaca for tests such as culture for microorganisms, parasite examination, or faecal occult blood determination; or can be collected for culture and molecular-based diagnostics from the rectum/cloaca using cotton, dacron, or gauze-tipped swabs, dependent on the volume of sample required by the specific test methodology. Samples collected on swabs should be kept moist by placing them in the transport media recommended for use with the specific test to be performed, which may range from sterile saline to culture media containing antimicrobials or stabilisers. Faecal specimens should be kept chilled (e.g. refrigerated at 4°C or on ice) and tested as soon after collection as possible to minimise the negative impacts on test results caused by death of the targeted microorganism, bacterial overgrowth or hatching of parasite eggs. Double-packaging of faecal samples in screw cap or sealable containers that are subsequently contained within sealed plastic bags will help prevent cross-contamination of samples and associated packaging materials. Faeces contained only in rectal exam gloves, plastic bags, or rubber-stoppered tubes are unsuitable as they are very frequently comprised by bacterial growth with gas production that can rupture plastic bags, displace stoppers, and allow leakage of the specimen.

4. Epithelium

Epithelial tissue in the form of biopsies or skin-scrapings; swabs of oral, nasal, pharyngeal, and gastrointestinal surfaces, as well as plucked hair or wool can be used variously for direct examinations or laboratory tests to identify surface parasites such as mites and lice, fungal, bacterial or viral infections, allergic reactions, and neoplasia. The specimens should be collected aseptically and preserved as specified for the intended test(s). Deep skin-scrapings obtained using the edge of a scalpel blade are useful for burrowing mites. Feather tips have been validated for use in the detection of viral antigen for Marek's disease, and used as a sample for molecular detection of additional avian diseases. Epithelial tissues, particularly those associated with vesicular lesions and collected into viral transport media, can be critical in the laboratory diagnosis of specific viral infections such as foot and mouth disease.

5. Ocular sampling

The surface of the eye can be sampled by swabbing or ocular scraping, ensuring that cells rather than mucopurulent discharge or lacrimal fluids are collected for testing. Specimens from the conjunctiva are typically collected by holding the palpebra apart and gently swabbing the surface of the eye with a cotton, dacron, or gauze swab that has been pre-moistened with sterile saline or equivalent media. Such swabs should be kept moist in saline or transport

media specifically recommended for use with the testing to be performed. Biopsies from the third eyelid of sheep have been used as a lymphoid-rich tissue for prion detection.

6. Sampling the reproductive tract

Preputial and vaginal wash fluids and swabs of the cervix and urethra can be used as specimens for investigation of reproductive disease. The swabs should be kept moist following collection by placing in the recommended volume of transport media required by the laboratory test, typically sterile saline or specified culture media. Semen specimens are typically obtained using an artificial vagina or by extrusion of the penis and artificial stimulation. Avoid contamination of the specimen with antiseptic or detergent solutions used to prepare the animal/site for sampling.

7. Nasal discharge, saliva, and vesicular fluids

Secretions can be collected directly into a vial or tube, or can be collected using swabs. Vesicular fluids provide a highly concentrated source of pathogen for diagnostic testing, and can be collected from unruptured vesicles using a sterile needle and syringe, and immediately transferred to a securely sealed vial or tube. Specifically developed sampling tools, such as probang cups, can be used for collecting cellular material and mucus from the pharynx of livestock. Cotton ropes that animals are allowed to mouth and chew have been validated for use in collecting saliva specimens from domestic swine.

8. Milk

Milk can be collected from individual animals or from bulk milk in tanks pooled from multiple animals in a herd. The teat(s) used for sample collection should be cleaned, and any detergent thoroughly rinsed off before collection of the specimen. In collecting milk from individual teats, the initial stream must be discarded and only the subsequent streams sampled. The method of preservation prior to testing varies with the requirements of the test; in some cases it will be critical to avoid freezing or addition of chemical preservatives. The individual disease chapters of this *Terrestrial Manual* or the advice of the testing laboratory should be consulted for appropriate specimen handling and preservation recommendations.

9. Tissues collected at necropsy

Necropsies should be conducted only by qualified veterinarians and pathologists. Paraveterinary staff may be trained by veterinarians to conduct post mortem examinations for specific purposes. Importantly, the purpose of the necropsy is not only to collect specimens but to make informed observations regarding the pathology of the condition. Such observations are an important adjunct to epidemiological and clinical observations in the comprehensive veterinary investigation of the case or outbreak. It is useful for veterinary authorities to retain specialist veterinary pathologists to lead post mortem investigations in important cases. Where this expertise is managed from a veterinary laboratory the methods employed should be formally described in the laboratory's Quality Assurance Manual and the capability should be recognised in the laboratory's scope of accreditation. Detailed procedures for conducting post-mortem examinations and tissue collection are available in most pathology text books, and are additionally provided in many of the web-page accessible national laboratory testing guidelines. Specimens that are critical for the laboratory investigation of listed diseases are included in the chapters of the *Terrestrial Manual* relating to each disease.

Whether the necropsy is performed in a designated laboratory facility or in the field, appropriate biosafety and containment procedures should be followed to ensure operator safety and to provide non-contaminated and useful tissues for testing as well as to protect the environment and other animals from potential exposure to pathogens. As a minimum requirement the collector(s) must wear personal protective equipment that protects the skin and mucous membranes and that can be discarded or decontaminated. All remaining tissues or carcass parts and fluids should be contained and treated with an appropriate disinfectant or destruction method, and the immediate environment should be thoroughly disinfected.

Dependent on the suspected disease, condition of the carcass and facilities available for necropsies post-mortem specimens can be collected from one or multiple organs and submitted to the laboratory as either fresh (no preservative) or preserved specimens for further laboratory testing. The process of carcass autolysis can destroy diagnostically relevant tissues and infectious agents and so should be considered prior to collecting and submitting post-mortem specimens.

For fresh specimens particular attention must be paid to their handling and storage to avoid autolysis and overgrowth by bacterial and fungal contaminants. Ideally, freshly collected specimens are kept at a constant cool temperature from collection until processing for testing. Where such a cold chain cannot be provided fresh specimens for some test procedures can be collected into fluids such as ethylene glycol that inhibit the growth of secondary organisms. Where such strategies are compatible with the subsequent test methods the option is mentioned in the relevant chapters of the *Terrestrial Manual* for each disease.

Preservation of post mortem specimens is most frequently achieved by collection into formalin solution. Where such chemical fixative is supplied to pathology staff by laboratories or competent authorities they must ensure adequate training in health and safety aspects of the use of such chemicals and training in compliance with regulations relating to the transport of such chemicals.

10. Environment and feed

Environmental sampling may be of litter, bedding, water from troughs and drinkers, or feed which has been exposed to urine, faeces, and/or saliva of affected animals, or swabbed surfaces of facilities, ventilation ducts, drains or feed containers. If specialised equipment is available circulating air may be sampled.

11. Honey bees

Adult moribund or recently dead bees can be collected in the vicinity of colonies. Live bees can be killed by freezing. Brood specimens are typically collected by removing a piece of brood comb showing abnormalities and including dead or discoloured brood followed by wrapping in a paper towel or newspaper rather than in foil or wax paper in order to help prevent microbial overgrowth. Alternately, diseased cells in a comb may be sampled using a toothpick or equivalent. A sticky board can be used to collect hive debris, including trapping of mobile parasites. More information on the specimens that need to be collected can be found in the disease-specific chapters of this *Terrestrial Manual* related to bees.

B. EPIDEMIOLOGICAL APPROACHES TO SAMPLING

To provide scientifically and statistically valid results specimens must be appropriate for the intended purpose for the proposed investigation, and adequate in quality, volume, and number. The range of purposes for which investigations supported by laboratory testing may be conducted have been outlined in Section A above.

For the purpose of laboratory testing to establish a diagnosis it is important to sample animals that are either clinically affected, or suspected on good evidence to be infected or, for serology, to have been infected. Specimens that are most likely to give highest sensitivity and specificity to the investigation should be collected. In general, the stage of infection, as well as the route and duration of shedding will determine the appropriate animal(s), stage of clinical disease, timeline for sampling, and tissue or anatomical site for sampling. These criteria will be addressed through an understanding of the pathogenesis of the disease for known conditions and on an hypothesis of the pathogenesis of the diseases for conditions of unknown aetiology.

To detect evidence of infection in line with the other five purposes of testing as listed in Section A above the sampling should be done within the context of a surveillance programme. The criteria for the design and implementation of effective surveillance are described in Chapter 1.4 *Animal health surveillance* of the *Terrestrial Animal Health Code* (*Terrestrial Code*). Identification of animals for sampling in surveillance programmes may be targeted (risk-based) or random. Risk-based sampling based on epidemiological knowledge of the infection under study or on epidemiological observations of the population under study is intended to result in the most likely detection of infected individuals.

Inferences on the status of a population such as estimation of prevalence, immune status or disease freedom should be based on random sampling. Random sampling ensures that the animals sampled are representative of the population, within the practical constraints imposed by different environments and production systems. Additionally, random sampling allows extrapolation of the findings of the study to the overall population (with an appropriate confidence interval). The epidemiological principles for sample size estimation are addressed in Appendix 1.1.2.1.

The specific requirements for surveillance to demonstrate freedom from disease/infection, and the associated sampling requirements, are addressed in detail in Article 1.4.6 of Chapter 1.4 of the *Terrestrial Code*.

Sampling and laboratory testing may also be used in support of epidemiologically based diagnostics and studies such as case control, structured longitudinal, and cohort studies (Fosgate & Cohen, 2008; Mann, 2003; Pfeiffer, 2010). The number and selection of the animals to be sampled and the nature of the specimens will be part of the study design.

C. INFORMATION TO BE SENT WITH SPECIMENS

Individual specimens must be clearly identified using appropriate methods. Marking instruments should be able to withstand the condition of use, i.e. being wet or frozen. Use of an indelible marking pen is required. Pencil may rub off containers. Labels attached to plastic may fall off when stored at –70°C.

Information regarding the location and contact information of the submitter and the premises sampled, the case information and associated epidemiological information, as detailed below, should always accompany the specimens to the laboratory. Such documentation should be placed in a plastic envelope on the outside of the shipping container so as to be available for reference during transport and should also be duplicated inside the shipping container between the secondary and the outer packaging (see also Chapter 1.1.3 *Transport of biological materials*). It would be advisable to contact the receiving laboratory to obtain an appropriate submission form and other relevant shipping and handling information.

Necessary information includes:

1. Location and contact information

i) Name and address of owner/occupier of the animal owner and/or the sampled premises and the geolocation (latitude and longitude, if available) where disease occurred, with appropriate contact information (telephone number, e-mail address).

ii) Name, postal and e-mail address, telephone and fax numbers of the sender.

2. Case information

i) Disease agents suspected and tests requested.

ii) Species, breed, sex, age and identity of the animals sampled, and trackability number when available.

iii) Date samples were collected and submitted.

iv) List and type of samples submitted with transport media used.

v) Case history:

   a) The clinical signs and their duration including the temperature of sick animals, condition of mouth, eyes and feet, and milk or egg production data as relevant.

   b) A list and description of the animals examined and the findings of the ante- and post-mortem examinations.

   c) The length of time sick animals have been on the premise; if they are recent arrivals, from where did they originate.

   d) The date of the first cases and of subsequent cases or losses, with, for tracking, any appropriate previous submission reference numbers.

3. Epidemiological information

i) A description of the spread of infection in the herd or flock.

ii) The number of animals on the premise by species, the number of animals dead, the number showing clinical signs, and their age, sex and breed.

iii) The type and standard of husbandry, including biosecurity measures and other relevant factors potentially associated with the occurrence of cases.

iv) History of foreign travel by owner or of introduction of animals from other countries or regions.

v) Any medication given to the animals, and when given.

vi) Vaccination history describing the type of vaccines used and dates of application.

vii) Other observations about the disease, husbandry practices and other disease conditions present.

D. RECEIPT, STORAGE AND ARCHIVES OF LABORATORY SUBMISSIONS

1. Reception of samples

Receiving, unpacking and aliquoting specimens must be done in a way to avoid cross-contamination in order to guarantee reliable testing of samples and prevent exposure of personnel.

A risk assessment (RA) as outlined in chapter 1.1.4 should be performed before systems for handling biological agents and toxins are established in order to define the appropriate biosafety and laboratory biosecurity measures. The RA should lead to the development of stated policy and procedures for the operation of the whole process of receiving submissions to the laboratory.

Submissions delivered to the laboratory should be received in accordance with specified standard operating procedures by staff who are appropriately trained, and when possible are made aware of potential arrivals so that parcels are treated correctly upon reception. To enable appropriate specimen tracking the following information should be logged: a) the time of arrival, b) the sender, c) the person receiving the samples, and d) the shipper with the tracking number. Where a specified chain of custody is required for the purposes of legal action or investigation the consignment should remain unopened and secured in a cool, dry place away from direct sunlight until authorised laboratory personnel are notified and available to receive the package and continue chain of custody. Laboratories should have a written operating procedure detailing the requirements to meet national legal requirements for such submissions.

1.1. Specimen reception area

Specimen reception areas should be equipped to facilitate the safe handling and processing of diagnostic submissions to avoid contamination of the work area, the personnel, cross-contamination among specimens and to allow easy disinfection in situations where specimen containers may have leaked. The specimen reception room should be clean with adequate bench space for organising submissions and paperwork. Depending on the number of submissions expected and depending on the RA the specimen reception area may be either a dedicated part of the diagnostic laboratory or a separate space outside the diagnostic laboratory.

The receiving room should contain an area dedicated to the unpacking of the specimens, with easily cleanable surfaces and trays and/or a biosafety cabinet, depending on the RA. There should be adequate and appropriate space to store specimens, either refrigerators or freezers, taking into consideration the time the specimens are to be stored. Specimen registration equipment such as computers, printers or logbooks should be available. A bar code system can be used to identify and track the specimens.

1.2. Submission unpacking, registration and preparation for further processing

Consignments should remain unopened until transferred to the specimen reception area for further processing. The submission should be unpacked and opened according to defined standard operation procedures. Surface decontamination should be considered to avoid cross-contamination and be part of the designated procedures arising from the RA.

Information to be recorded at specimen log-in includes the delivery source, the date the submission was consigned, the condition of the outer package, and the condition of inner packages (noting the presence of leaks or breakage), the condition of the specimen material, the inner package temperature, and any specific requests from the sender.

Further activities may include labelling of specimen containers, transfer of specimens to the laboratory and storage of specimens.

Packaging material should be disposed of appropriately according to national regulations which may include autoclave destruction of all packaging materials, depending on the RA.

Personal protective equipment (PPE) should be provided to protect the personnel. Minimal PPE is a laboratory coat and gloves. Depending on the relevant RA respiratory protection or effective splash protection (e.g. protective glasses) may be required as well.

After it has been determined that the submission contains the appropriate paperwork matching the specimens and that the specimens are in good condition appropriately trained laboratory personnel become responsible for transfer to the appropriate laboratory area, including maintenance of the chain of custody of the specimens as required. Only properly contained registered (identified) specimens should be transferred into the diagnostic laboratory. It is good practice, and at times a requirement for biosafety and laboratory biosecurity dependent on the RA, to enclose the submitted specimen containers in a secondary container to transfer the specimens safely within the laboratory.

1.3. Emergencies

A comprehensive RA will identify credible and foreseeable emergency scenarios, and be the basis for preparing a response plan. In particular, leaky samples represent a biohazard for the laboratory personnel and could contaminate the environment and other samples. Written instructions on how to deal with broken or leaky tubes should be available in the sample reception area. Personnel should be trained and regular emergency exercises and simulations should take place.

Samples that are degraded or in a condition unacceptable for testing should be decontaminated and appropriately disposed of according to the laboratory's response plan as noted in the prior paragraph. Contaminated laboratory surfaces should be decontaminated with the appropriate disinfectant. Sample rejection and discrepancies between the sample and accompanying paperwork should be resolved by contacting the sender immediately to resend a duplicate sample or to clarify paperwork.

2. Storage and archives

Collections of well characterised specimens including infectious agents, infected tissues and fluids, as well as negative control tissues and fluids, are critical for future research and development efforts, for retrospective studies, epidemiological investigations, and for providing critical reference materials used in assay standardisation, validation, and proficiency testing programmes. In addition, specimens being investigated for legal purposes should be banked.

Materials routinely needed as reference standards and for assay validation are described in Chapter 1.1.5 *Quality management in veterinary testing laboratories*. The materials maintained in laboratory archives should be representative of the agents handled and the types of samples used in the different testing methods performed, which would variously include fresh and fixed tissues and fluids, paraffin-embedded tissues, and stabilised or otherwise preserved cultures. The World Federation for Culture Collections (WFCC: *www.wfcc.info/collections*) is a useful source of information and reference documentation for developing, maintaining, and sharing culture collections, and has published a comprehensive guide for establishing and operating microbial culture collections (WFCC, 2010). It is part of the remit of WOAH Reference Laboratories to supply reference materials.

The principal components of any laboratory archive include the appropriate means of stabilisation and storage, a complete system of documentation and inventory of the material stored, and implementation of biosafety and laboratory biosecurity measures needed to manage the collection.

2.1. Stabilisation and storage

The method of preserving tissues, fluids, and cultures will depend on their anticipated use(s). Samples stored for periodic access such as assay reference materials should be aliquoted to avoid potential problems associated with repeated retrieval and return to storage. They may be stored separately from specimens or samples stored for historical, long-term preservation. Storage conditions should be managed to maintain viability, biochemical, and immunological properties of the samples to the

maximum extent possible. Considerations for preserving the integrity of the samples must include protection from desiccation (e.g. as can happen in certain freezers), frequent or extreme temperature fluctuations, UV degradation, humidity, contamination, and the potential for loss of identification and associated archive documentation. Unique or valuable isolates and materials should be stabilised and stored using at least two different procedures and storage locations.

Storage at ultra-low temperatures (e.g. liquid nitrogen, cryopreservation in freezers at –140°C or lower) is considered the optimum method for long-term storage of biological materials. Storage at low-freezer temperatures of –80°C and –20°C is common for periods that may range from months to 5–10 years. Ultra-low freezing may not be a practical choice as it is expensive to maintain, but cost must be balanced with the fact that biological degradation of the sample over time is an increasing risk at warmer freezer temperatures. Reference materials that are to be accessed with any regularity should be stored in appropriately-sized aliquots to allow access while minimising the number of times the "master stock" is handled. Repeated freezing and thawing of samples should be avoided as it can denature antigens, result in loss of viability of fastidious agents, and can precipitate the over-growth of contaminants or unwanted microorganisms in the sample.

Methods for stabilisation and storage of samples at room temperature range from commercially available technologies that largely target nucleic acid stabilisation, lyophilisation processes, to the relatively low-tech versions of drying fluids on filter paper disks or storage of biological samples in the presence of desiccating agents such as silica gel or grains of rice to absorb moisture.

Considerations such as speed at which a sample is frozen or chemically preserved, size and density of the material to be preserved, storage container and media, and also protocols for reconstitution, thawing, and reviving agents will vary with different tissues and agents. Whether the plan is to store samples frozen or at ambient temperature, for most tissues and groups of infectious agents there are specific preservatives, stabilisation protocols, and storage conditions that are considered optimal; the current published literature should be consulted.

2.2. Documentation and Inventory

Agents and tissues maintained in an archive must be correctly identified and sufficient supporting data that characterises the sample or agent must be recorded. For reference materials, further documentation that authenticates the agent or tissue is required. The unique identity of the tissue, fluid, or agent and the storage location are best maintained in an electronic or paper inventory record which also documents the date the material was obtained, date and method of preservation, volume of material stored, source of the material including associated species, geographical location, and the clinical history of the donor animal and the disease situation of the flock or herd. Additional information is extremely useful and generally includes the original method of isolation/recovery, characterisation (e.g. available data on biochemical properties, antibody or antigen titre, and genetic sequence) as well as additional history on handling of the material (e.g. number of passages for infectious agents and cell lines, dates the archived material was frozen-thawed or rehydrated and the dates it was transferred to different storage conditions or containers). Inventories are most often organised by assigning a unique identifying number or alphanumeric code to each sample (sample container) that is cross-referenced to a database or inventory log. Inventory records can be manual data logs, computerised spreadsheets, or specialised computer programs. However the records are managed, they must be kept current and the information entered must be traceable to its source. The identification of the individual making an entry or modification to the sample inventory should be recorded.

2.3. Biosafety and laboratory biosecurity

As a first step in establishing an archive, a laboratory biorisk assessment addressing biosafety and laboratory biosecurity issues, including any control or mitigation measures to be implemented, must be completed. As further defined in chapter 1.1.4, an appropriate risk assessment for archived samples should address the technical competency needed of staff handling the tissues, fluids, and agents, with particular emphasis on those materials that are potentially infectious or toxic to workers, animals, and the environment in and around the laboratory. The laboratory should consider all biorisk management measures needed to protect the integrity of the sample, as well as the health of the workers and environment, from the time the original sample is received through the long-term storage and ultimate use or destruction of the material(s).

The appropriate level of laboratory biosecurity, including controlled access to the archived samples and inventory records, is an important consideration for laboratories maintaining biological inventories and archives. The laboratory should also have a back-up plan for the transfer or destruction of potentially dangerous archived materials in the event of power failures or other compromises to the storage environment. National and international regulations and legislation, including requirements for permits and licenses to receive, maintain, work with, and distribute specific agents and tissues must be followed for all laboratory archives. Current regulatory information in regards to receiving and storage of biological materials can be found on the European Biological Resource Centre Network website (www.ebrcn.net/), in the WFCC guidelines (2010) and from relevant national government agencies.

MOST RECENT UPDATES ADOPTED IN 2013.

APPENDIX 1.1.2.1.

EPIDEMIOLOGICAL APPROACHES TO SAMPLING: SAMPLE SIZE CALCULATIONS

The type and number of samples needed depends on the desired purpose. Sample size calculation for each of the main purposes of testing, where random sampling has been used, may be approached as follows:

1. Demonstrate freedom from infection in a defined population (country/zone/ compartment/herd where the prevalence is apparently zero)

Frequently, the objective of sampling is to determine if a disease is present or absent in a population at a specific threshold (design prevalence). These sampling methods are needed to perform the scientifically based surveys specified in the WOAH *Terrestrial Animal Health Code* in order to determine freedom with and without vaccination as well as to re-establish freedom after outbreaks.

It is possible to calculate how many animals should be sampled from a herd/flock of a certain size, to achieve a 95% probability of detecting infection or previous exposure assumed to be present in a certain percentage of the animals. The following formula can be applied:

$$n \cong \frac{(1-(1-CL)^{1/D})(N-{}^{1}/_{2}\,(SeD-1))}{Se}$$

Where
n: is the required sample size
CL: is the confidence level (generally 0.95)
N: is the population size
D: is the number of diseased animals expected in the population
Se: is the diagnostic sensitivity of the test used

For example, to determine the sample size required to detect with 95% confidence at least one infected animal in a herd of 500 animals at a design prevalence of 10%, the formula above would be used as follows (assuming perfect diagnostic sensitivity):

$$n \cong (1-(1-0.95)^{1/50})(500-{}^{1}/_{2}\,(50-1)) \cong 28$$

If the laboratory results are negative for all samples the epidemiologist can conclude, with 95% confidence, that the prevalence is lower than 10%. If the disease in question is highly infectious and it is unlikely that only 10% of the animals would be infected, the herd could be considered free. If, however, one or more samples are positive the epidemiologist may conclude, with 95% confidence, that the disease prevalence is at least 10%.

2. Certify freedom from infection or presence of the agent in individual animals or products for trade/movement purposes

The *Terrestrial Code* provides specific recommendations for trade purposes. Some are based on demonstration of disease freedom at a herd or flock level and others on testing of individual animals for export. When certification of a disease free herd or flock is recommended, the approach described in point 1 above can be followed to calculate the number of samples required.

In the case of testing individual animals, it is generally expected that all animals will be tested. The critical question in this case is related to the negative predictive value (NPV) of the test and the probability of having at least one false negative individual in a group. The negative predictive value of a test is defined as the probability that an animal

is not infected given that it tested negative. The NPV is a function of the diagnostic sensitivity and specificity of the test(s) used and the prevalence of the infection in the population where the animals come from. In general, the probability of having at least one false negative in a group is calculated as:

$$P(x \geq 1) = 1 - (1 - NPV)^n$$

The negative predictive value is calculated as follows:

$$NPV = \frac{TN}{TN + FN} = \frac{(1-p)Sp}{(1-p)Sp + p(1-Se)}$$

Where
TN: is the true negative
FN: is the false negative
Se: is the diagnostic sensitivity
Sp: is the diagnostic specificity
p: is the prevalence
n: is the number of animals in the group

Additional information on quantifying these types of probabilities can be found in the WOAH *Handbook on Import Risk Analysis for Animals and Animal Products, Quantitative Risk Analysis*.

3. Eradication of disease or elimination of infection from defined populations

The objective of surveillance in the event of an outbreak is to try to find any remaining pockets of infection. Sampling should be directed at populations having higher risk of exposure and where the agent is most likely to be found, such as animals exhibiting clinical signs or suspected to have been in contact with infected animals. If animals within a selected herd or flock are not exhibiting clinical signs, a representative sample, based on the formula presented under point 1 above for presence or absence of disease, should be collected.

4. Confirmatory diagnosis of suspect or clinical cases (includes confirmation of positive screening test)

Suspect or clinical cases with a positive screening test result should be retested with a confirmatory test. Usually, a test with high diagnostic sensitivity is used for screening purposes and one with high diagnostic specificity for confirmation. If the status of the herd or flock is of interest, animals exhibiting clinical signs compatible with the disease of interest should be sampled. This will increase the probability of confirming the infection. If required, the formula for presence or absence in point 1 above can be used to calculate the number of samples required. Given that sample collection is directed to animals exhibiting clinical signs, the design prevalence used can be relatively high, yielding a lower sample size.

5. Estimate prevalence of infection

Disease control programmes may need to periodically assess the impact of control measures. One of the key indicators of success is a reduction in the prevalence of the disease. To determine the prevalence of disease within a group of animals, the following formula can be used to determine the number of samples required.

$$n = \frac{Z^2 pq}{L^2}$$

Where
n: is the required simple size
Z: is the value of the Z distribution for the desired confidence level (usually 95%)
p: is the expected prevalence in the population
q: is 1-p
L: is the level of precision (or acceptable error)

There are no fixed rules to determine the level of precision (sometimes called also margin of error), the choice of it is left to the epidemiologist conducting the survey. However, finer levels of precision require larger sample sizes.

The corresponding value of the Z distribution for 95% confidence is 1.96. To determine the prevalence of a disease with 95% confidence in a herd of 500 animals with an expected disease prevalence of 20%, at a level of precision of ±3%, the required sample size can be calculated:

$$n = \frac{1.96^2 \times 0.2 \times 0.8}{0.03^2} = \frac{0.6146}{0.0009} \cong 683$$

Note that in this case the required sample size is larger than the population, so the sample size will need to be adjusted to take account the population size (N):

$$n_{adj} = \frac{1}{1/n + 1/N} = \frac{1}{1/683 + 1/500} \cong 289$$

Therefore, 289 animals would have to be randomly sampled.

6. Determine immune status of individual animals or populations (post-vaccination).

Disease control programmes often rely on vaccination as a tool, in such cases it is important to assess immunity coverage and not merely count the number of animals or herds that have been vaccinated. The proportion of animals that need to be immunised to stop the spread of disease in a population is a function of the number of secondary infections arising from a single infected case (the reproductive number, R_0). For many infectious diseases the proportion needing immunity in order to control, disease spread is around 80%. Two approaches can be applied. If the objective is finding the proportion of immune animals, the formula for determining prevalence in point 5 above, can be applied. If, however, programme managers want to assess if herds have an immunity level at or above a certain threshold, the formula for presence or absence, in point 1 above, should be used. The difference in sample size varies greatly depending on the objective.

If the immune status of a herd of 500 animals that have all been vaccinated wants to be estimated, the following approaches can be followed.

6.1. Estimating the proportion of immune animals in a group

- Expected prevalence (of immune animals) 80%
- Precision, for this example assume 3%
- Confidence level 95%

$$n = \frac{1.96^2 \times 0.8 \times 0.2}{0.03^2} = \frac{0.6146}{0.0009} \cong 683$$

$$n_{adj} = \frac{1}{1/n + 1/N} = \frac{1}{1/683 + 1/500} \cong 289$$

6.2. Estimating immunity at a defined threshold

- Expected prevalence (of immune animals) 80%, i.e. 400 out of 500 animals
- Confidence level 95%
- Perfect diagnostic sensitivity

$$n \cong (1 - (1 - 0.95)^{1/400})(500 - 1/2\,(400 - 1)) \cong 3$$

If at least one of the three samples is positive to the test, the interpretation is, with 95% confidence, that the proportion of immune animals in the herd is at least 80%. If none of the samples test positive, the herd cannot be considered adequately immunised. Such an approach can be used to determine geographical locations or types of production systems where immune coverage is low and might need to be re-vaccinated.

CHAPTER 1.1.3.

TRANSPORT OF BIOLOGICAL MATERIALS

INTRODUCTION

The transport of biological materials, including infectious substances, is covered by international, regional or national regulations that are updated on a regular basis and are widely accessible via the internet, or through commercial and regulatory transportation affiliates. The transport of biological materials within a country and between countries will be explained in this chapter.

The international regulations for the transport of infectious substances by any mode of transport are based upon the Recommendations on the Transport of Dangerous Goods made by the Subcommittee of Experts on the Transport of Dangerous Goods (UN SCETDG), a subcommittee of the United Nations Economic and Social Council. The Recommendations are presented in the form of Model Regulations covering air, rail, road, sea and also include international mail. The World Health Organization (WHO) guidance document on "Transport of Infectious Substances" summarising the different transport regulations is regularly updated. Countries, other international organisations, international treaties and conventions such as the International Air Transport Association (IATA), the World Customs Organization (WCO), the Convention on International Trade in Endangered Species (CITES), and the Convention on Biodiversity (CBD), especially the Nagoya Protocol, provide additional guidance and regulations that should be considered in planning the transportation of biological materials.

In the interest of animal and human health, biological materials collected from animals must be transported safely, efficiently and legally from the place where they are collected to the place where they are analysed, studied or used. The collection of specimens from animals is covered in Chapter 1.1.2 Collection, submission and storage of diagnostic specimens*.*

For the purpose of this chapter, animals are defined as all members of the Kingdom Animalia except humans, and biological materials include specimens or samples from animals, cell cultures, zoonotic and animal microorganisms and genetically modified or synthetic organisms, and biological products such as vaccines and reagents.

A. RESPONSIBILITIES

All personnel involved in the packaging, labelling and shipping of biological materials must be appropriately trained, certified, competent and knowledgeable of the relevant national, regional and international regulations.

Biological materials should be transported to ensure a rapid and reliable system for delivery to the recipient using individuals such as professional logistics service providers that are trained and competent in the shipping and transportation process.

The efficient transport and transfer of biological materials requires co-ordination between the sender (shipper, consignor), the logistic providers, the carrier and the recipient (consignee) to ensure safe transport and arrival on time and in proper condition.

The sender (shipper, consignor) is responsible for providing the applicable documentation (e.g. certifications, permits) required by the national authorities of the countries of export, transhipment and import as well as ensuring that the shipment also complies with all other applicable regulations, such as:

i) Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization to the Convention on Biological Diversity (CBD): Biological material containing genetic

resources as defined under the CBD may be subject to Access and Benefit-Sharing legislation in both the country where it is sourced and the country where it is sent.

ii) CITES (Convention on International Trade in Endangered Species of Wild Fauna and Flora): All import, export, re-export and introduction from the sea of species covered by the Convention has to be authorised through a licensing system. Resolution Conf. 12.3. (Rev.CoP17) on Permits and Certificates, contains a section XII, regarding the use of simplified procedures to issue permits and certificates (https://cites.org/sites/default/files/document/E-Res-12-03-R17.pdf).

Procedures for incidents such as spills or theft of materials during transportation and any other realistic and foreseeable emergencies should be part of a risk management system in order to respond adequately to emergencies (for basic principles see Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*).

1. The sender (shipper, consignor)

i) Before any shipment of biological materials, the sender must be able to:

   a) Identify and classify, pack (including temperature control), ensure quantity limits, mark and label the package of biological materials,

   b) Ensure the correct documentation of all biological materials intended for transport,

   c) Complete and produce a Shipper's Declaration for Dangerous Goods (DGD), when required,

   d) Ensure biological materials are not forbidden for transport;

ii) Prepares necessary documentation, including permits, dispatch and shipping documents if necessary;

iii) Notifies the recipient of transportation arrangements once these have been made, well in advance of the expected arrival time;

iv) The air way bill (AWB) is the standard shipping document for shipping goods by air. While it is common practice for the air carrier or freight forwarder to complete the air waybill, the sender may be required to provide it;

v) Makes advance arrangements with the recipient including investigating the need for import/export permits;

vi) Makes advance arrangements with the carrier to ensure:

   a) that the shipment will be accepted for appropriate transport;

   b) that the shipment is undertaken by the most direct routing, as appropriate.

2. The carrier/courier

i) The following measures must be taken by the carrier:

   a) Routing: appropriate routing must be ensured, such as by the shortest or most secure route.

   b) Transhipment: when transfers are necessary, precautions must be taken to assure special care, expeditious handling and monitoring of the substances in transit for both safety and security purposes.

ii) For air transport, the carrier is required by the regulations to use, when applicable, an acceptance checklist to verify that the shipment complies with:

   a) marking and labelling requirements; and

   b) documentation requirements.

iii) Provide advice to the sender and assistance regarding the necessary shipping documents and instructions for their completion as well as correct packaging

iv) Assists the sender in arranging the most appropriate routing and then confirms the routing and provides, if possible, ways to track the shipment;

v) Maintains and archives documentation for shipment and transport.

3. The recipient (consignee)

i) Obtains the necessary authorisation(s) from national authorities for the importation of the material;

ii) Provides the sender with the required import permit(s), letter(s) of authorisation, or other document(s) required by the national authorities;

iii) Arranges for the most timely and efficient collection on arrival;

iv) Should acknowledge receipt to the sender.

Shipments should not be dispatched until all the necessary arrangements between the sender, carrier and recipient have been made.

The transportation chain involves many more stakeholders with specific roles and responsibilities. These are explained in more details in the framework of aviation security in a joint ICAO (International Civil Aviation Organization) and WCO (World Customs Organization) brochure that can be accessed using the following link: http://www.wcoomd.org/en/topics/facilitation/instrument-and-tools/tools/~/media/4B167884A3064E78BCF5D29E29F4E57E.ashx.

In addition, Material Transfer Agreements (MTA) should be considered because they:

i) Protect the interests of all involved parties in relation to;
   a) Intellectual property
   b) Potential alternative uses
   c) Commercial aspects
   d) Liability to third parties
   e) Potential further transfers/uses

ii) Help to avoid misunderstandings around the use of materials

iii) Clarify ownership of property

With reference to Article 4 of the "Nagoya Protocol on Access to Genetic Resources and the Fair and Equitable Sharing of Benefits Arising from their Utilization (ABS) to the Convention on Biological Diversity", the MTA is intended to establish a platform for the open exchange of materials among laboratories and to constitute Prior Informed Consent (PIC) on Mutually Agreeable Terms, while avoiding as much as possible the potential adverse impacts of the Nagoya requirements.

Appendix 3 is provided as a generic template for use in transfer of materials. It is intended to be modified and adapted as required to meet individual circumstances.

Appendix 3 does not constitute legal advice and users are responsible to ensure it meets their objectives and fulfils requirements of local legislation. Users are encouraged to consult their own legal professionals for advice on use of this template.

B. CLASSIFICATION AND CATEGORISATION

When transporting biological materials, the sender must determine whether the material should be classified as dangerous goods or not. Dangerous goods (hazardous materials, HAZMAT) are materials that can harm humans, animals and other living organisms, property, or the environment, and their transport is regulated by United Nations (UN) regulations[1]. Dangerous goods are assigned a *UN number* and *proper shipping name* based on the classification of the dangerous goods. The transport regulations assign a packing instruction against the UN number and proper shipping name, to specify the packaging/packing method to ensure that the dangerous goods do not pose a hazard in transport. Of the biological materials that are discussed in this Chapter, infectious substances are classified as dangerous goods and are assigned to UN 2814, UN 2900, UN 3373, or UN 3291, as

1 http://www.unece.org/trans/danger/publi/unrec/rev13/13nature_e.html; http://www.unece.org/trans/danger/publi/unrec/rev20/20files_e.html

appropriate. In addition, Genetically Modified Microorganisms (GMMOs) and Genetically Modified Organisms (GMOs) are classified as Class 9 and assigned to UN 3245 if they are not classified as Category A or Category B.

Table 1. Summary of classification, categorisation, identification and packaging of infectious substances

Dangerous goods classifications	Categorisation	Proper shipping name[2]	UN number[2]	Packing instruction/ packaging requirements
Class 6, Division 6.2	Category A	Infectious substance, affecting humans	UN 2814	P620
		Infectious substance, affecting animals	UN 2900	
Class 6, Division 6.2	Category B	Biological substance, Category B	UN 3373	P650
Class 6, Division 6.2	Exempt human/animal specimens	Exempt human/animal specimens	N/A	Triple packaging
not subject to dangerous goods regulations	Biological materials not subject to dangerous goods regulations	N/A	N/A	N/A
Class 9	GMMOs and GMOs that are not classified as Category A or B infectious substances	Genetically modified microorganisms; Genetically modified organisms	UN 3245	P904 (ICAO/IATA PI 959), IBC99

If it is likely that microorganisms that are present in the biological materials can cause harm to humans or animals then they must be assigned either to Category A or B.

The proper shipping name (see Table 1) must be supplemented with the technical name (scientific name of the pathogen) in parenthesis on the transport document, but not on the outer packaging. When the identity of the infectious substances to be transported are unknown, but are suspected of meeting the criteria for inclusion in category A, the words “suspected category A infectious substance” must be shown, in parenthesis, following the proper shipping name on the transport document.

1. Category A

A Category A substance is an infectious substance which is transported in a form that, when exposure to it occurs, is capable of causing permanent disability, life-threatening or fatal disease in otherwise healthy humans or animals. Assignment to UN 2814 or UN 2900 (see Table 1) must be based on the known medical history of the animal(s), signs and individual circumstances of the specimen source, and endemic local disease conditions, or professional judgement concerning individual circumstances of the source, human or animal.

Some organisms are considered Category A only when in culture form (e.g. *Bacillus anthracis*, foot and mouth disease virus). Indicative examples of substances that meet these criteria are given in the Table 3. The table is not exhaustive. Infectious substances, including new or emerging pathogens, which do not appear in the Table but which meet the same criteria must be assigned to Category A. In addition, if there is doubt as to whether or not a substance meets the criteria it must be assigned to Category A.

Some infectious substances may have a high economic or trade impact on specific countries should there be release to the environment. Therefore, other infectious substances may be added to the list by individual countries (e.g. cultures of Newcastle disease virus where the virus is exotic to the country or region).

2 Dangerous goods are assigned UN numbers and proper shipping names according to their hazard classification and condition under the Dangerous Goods Regulations. See the Dangerous Goods List at pages 191–304 of the UN Model Regulations http://www.unece.org/fileadmin/DAM/trans/danger/publi/unrec/rev20/Rev20e_Vol1.pdf

Medical or clinical waste containing Category A infectious substances shall be assigned to UN 2814 or UN 2900 as appropriate. **Solid** medical waste containing Category A infectious substances generated from the medical treatment of humans or veterinary treatment of animals may be assigned to UN 3549. It should be noted that Medical or clinical waste from bio-research or liquid waste must not be assigned to UN3549.

2. Category B

Biological materials containing pathogens which do not meet the criteria for Category A (i.e. do not cause life-threatening disease to humans or animals) shall be assigned to Category B (UN 3373).

Typically a specimen with a high likelihood to contain pathogenic organisms shipped for disease diagnosis (e.g. confirmatory diagnosis of suspected or clinical cases, specimens for differential diagnosis, such as blood samples for classical swine fever or sheep pox diagnostics or throat samples from chickens for avian influenza) can be assigned to Category B.

It is important to note that unlike cultures, *patient specimens* which may contain infectious microorganisms listed as 'cultures only' in Table 3 (Category A infectious substances) do not require Category A transport practices. For these specimens Category B transport practice should be applied. In this case, although directly collected specimens (e.g. serum) can be shipped as Category B, pure cultures of the same pathogens must follow the requirements of Category A due to the characteristics of the specific organism. Some examples are classical swine fever virus isolates or sheep pox virus isolates (see Table 3). Specimens from animals intentionally infected with Category A pathogens must be sent as Category A, even if they are assigned to Category A (cultures only).

Shipments of cultures of non-category A agents can be assigned to Category B.

Medical or clinical waste containing Category B infectious substances shall be assigned to UN 3291.

3. Exempt specimens

Animal specimens for which there is minimal likelihood that pathogens are present can be transported as Exempt Specimens. Examples of specimens in the veterinary field which may be transported as exempt include specimens from surveillance studies, export controls of healthy animals (e.g. certification of freedom from classical swine fever) or determination of immune status of individual animals or populations (post-vaccination).

These specimens are not subject to dangerous goods regulations if the specimen is transported in a packaging that will prevent any leakage and that is marked appropriately (triple packaging principle, see item C and Figure 3 of Appendix 1.1.3.2).

4. Biological materials not subject to Dangerous Goods Regulations

Based on the known medical history of the animal(s), signs and individual circumstances of the source of the biological materials, and endemic local disease conditions, the following *are not subject to dangerous goods regulations, unless they meet the criteria for inclusion in another class* (*such as Class 9*):

i) biological materials that do not contain infectious substances

ii) biological materials containing microorganisms that are non-pathogenic to humans or animals;

iii) biological materials in a form in which any pathogens present have been neutralised or inactivated such that they no longer pose a health risk;

iv) Environmental specimens (including food and water specimens) that are not considered to pose a significant risk of infection;

v) Dried blood spots, collected by applying a drop of blood onto absorbent material.

Note: There may be specific regulations in place in some countries for the shipment, export or import of nucleic acids.

5. Contaminated items

These listed below are also included in infectious substances in the international regulations on transport of dangerous goods, however the details are not discussed in this chapter. For more information see UN Model Regulations, paragraphs 2.6.3.2.3.3 and .9 respectively.

Table 2. Summary of classification, categorisation, identification and packaging of contaminated items with infectious substances

Dangerous goods classifications	Categorisation	Proper shipping name[3]	UN number[3]	Package
Class 6, Division 6.2	Category A	Medical* devices or equipment contaminated with or containing infectious substances in Category A	UN2814, UN2900 as appropriate	Must be marked "Used Medical Device" or "Used Medical Equipment"
Class 6, Division 6.2	Exemption when condition is met	Medical* devices, medical equipment	N/A	See UN Model Regulations 2.6.3.2.3.9 and IATA Dangerous Goods Regulations (DGR) 3.6.2.2.3.9
Class 6, Division 6.2	Category A	Medical* waste, Category A, affecting humans, **solid**; Medical waste, Category A, affecting animals only, **solid**	UN 3549	P622, LP622
Class 6, Division 6.2	Category B	Clinical waste, Unspecified, n.o.s.(not otherwise specified); (Bio) medical waste, n.o.s.; Regulated medical waste, n.o.s.	UN3291	P621 (PI622), IBC620, LP621

*including veterinary use

6. Infectious substances included in Category A

Table 3. Indicative examples of infectious substances included in Category A

UN number and proper shipping name	Microorganism
UN 2814 Infectious substance, affecting humans	*Bacillus anthracis* (cultures only)
	Brucella abortus (cultures only)
	Brucella melitensis (cultures only)
	Brucella suis (cultures only)
	Burkholderia mallei – glanders (cultures only)
	Burkholderia pseudomallei (cultures only)
	Chlamydia psittaci – avian strains (cultures only)

3 Dangerous goods are assigned UN numbers and proper shipping names according to their hazard classification and condition under the Dangerous Goods Regulations. See the Dangerous Goods List at pages 191–304 of the UN Model Regulations http://www.unece.org/fileadmin/DAM/trans/danger/publi/unrec/rev20/Rev20e_Vol1.pdf

UN number and proper shipping name	Microorganism
	Clostridium botulinum (cultures only)
	Coccidioides immitis (cultures only)
	Coxiella burnetii (cultures only)
	Crimean–Congo haemorrhagic fever virus
	Dengue virus (cultures only)
	Eastern equine encephalomyelitis virus (cultures only)
	Escherichia coli, verotoxigenic (cultures only)[4]
	Ebola virus
	Flexal virus
	Francisella tularensis (cultures only)
	Guanarito virus
	Hantaan virus
	Hantaviruses causing haemorrhagic fever with renal syndrome
	Hendra virus
	Hepatitis B virus (cultures only)
	Herpes B virus (cultures only)
	Human immunodeficiency virus (cultures only)
	Highly pathogenic avian influenza virus (cultures only)
	Japanese encephalitis virus (cultures only)
	Junin virus
	Kyasanur Forest disease virus
	Lassa virus
	Machupo virus
	Marburg virus
	Monkeypox virus
	Mycobacterium tuberculosis (cultures only)[1]
	Nipah virus
	Omsk haemorrhagic fever virus
	Poliovirus (cultures only)
	Rabies virus (cultures only)
	Rickettsia prowazekii (cultures only)
	Rickettsia rickettsii (cultures only)
	Rift Valley fever virus (cultures only)
	Russian spring–summer encephalitis virus (cultures only)
	Sabia virus

4 For surface transport (ADR) nevertheless, when the cultures are intended for diagnostic or clinical purposes, they may be classified as infectious substances of Category B.

UN number and proper shipping name	Microorganism
	Shigella dysenteriae type 1 (cultures only)
	Tick-borne encephalitis virus (cultures only)
	Variola virus
	Venezuelan equine encephalitis virus (cultures only)
	West Nile virus (cultures only)
	Yellow fever virus (cultures only)
	Yersinia pestis (cultures only)
UN 2900 Infectious substance, affecting animals only	African swine fever virus (cultures only)
	Avian paramyxovirus Type 1 – Velogenic Newcastle disease virus (cultures only)
	Classical swine fever virus (cultures only)
	Foot and mouth disease virus (cultures only)
	Lumpy skin disease virus (cultures only)
	Mycoplasma mycoides – contagious bovine pleuropneumonia (cultures only)
	Peste des petits ruminants virus (cultures only)
	Rinderpest virus (cultures only[5])
	Sheep-pox virus (cultures only)
	Goatpox virus (cultures only)
	Swine vesicular disease virus (cultures only)
	Vesicular stomatitis virus (cultures only)

C. PACKAGING

1. Principles

All biological materials should be packaged and transported in accordance with local, national and international regulations. The procedures should minimise the risk of exposure for those engaged in transportation and should protect the environment and susceptible animal populations from potential exposures. Additionally, ineffective packaging that does not protect specimens or preservatives (e.g. ice) from damage or prevent leakage will likely delay the delivery of the shipment to the laboratory, delaying or preventing critical laboratory analyses from being performed. Biological materials should always be packaged and transported to protect the integrity of the specimens, as well as to avoid cross-contaminating other specimens and environmental contamination. Minimum requirements for the transport of specimens follow the principle of triple packaging, consisting of three layers as described below:

i) a primary receptacle;

ii) a secondary packaging;

iii) an outer packaging;

of which either the secondary or the outer packaging must be rigid.

5 Subject to prior approval by the FAO-WOAH rinderpest secretariat

1.1. Primary receptacle

A primary receptacle, leak-proof for liquids or sift-proof for solids containing the specimen. Primary receptacle(s) must be packed into the secondary packaging with enough absorbent material (e.g. cellulose wadding, paper towels, house hold paper, cotton balls) to absorb all fluid in case of breakage. Even though the regulations do not prohibit glass, primary receptacles should preferably be non-breakable. In addition, they must not contain any sharps (e.g. vacutainer with needle), particularly when using soft secondary or outer containers. If screw cap vials are used, they shall be secured by e.g. tape. A flip-top vial must not be used.

1.2. Secondary packaging

A second durable, leak-proof packaging to enclose and protect the primary receptacle(s) (e.g. sealed plastic bag, plastic container, screw-cap can).

The primary receptacle or the secondary packaging shall be capable of withstanding, without leakage, an internal pressure of 95 kPa (0.95 bar) in the range of –40°C to +55°C (–40°F to +130°F).

1.3. Outer packaging

Secondary packaging is placed in outer shipping packaging (e.g. sturdy insulated fibre board box) with suitable cushioning material. Outer packaging protects the contents from outside influences, such as physical damage, while in transit.

2. Category A

Due to the highly hazardous nature of the Category A samples the packaging must meet special requirements. The principle of triple packaging applies here, and the transport containers and outer packaging must meet the criteria defined in the relevant regulations. Category A must only be transported in packaging that meets the United Nations class 6.2 specifications, complies with Packing Instruction P620 and have passed specific tests and with UN specification marking as P620. This ensures that strict performance criteria are met; tests for compliance with these criteria include a 9-metre (29.5 feet) drop test, a puncture test, a pressure test and a stacking test. The packages are labelled to provide information about the contents of the package, the nature of the hazard and the packaging standards applied.

Marking and labelling is as follows (see Fig. 3 of Appendix 1.1.3.2):

i) *The delivery address* (*consignee*) *and sender's details* (*shipper*), *as well as 24/7 emergency contact details including named persons with telephone numbers to guarantee safe delivery.*

ii) *The proper shipping name and the UN number.*

Proper shipping name	*UN number*
INFECTIOUS SUBSTANCE, AFFECTING HUMANS	*UN2814*
INFECTIOUS SUBSTANCE, AFFECTING ANIMALS only	*UN2900*

iii) *The Infectious Substance label* (*Figure 1*).

NB: This label is only for Category A. This label must not be used when shipping Category B.

Fig. 1. Infectious Substance label for the transport of Category A.

iv) *UN specification marking for P620 packaging (printed on the box).*

v) *Orientation label, Cargo only label, if required (depending on the Net Weight [kg] of the infectious substance in a P620 box).*

The exact details can be found in P620 Packing Instruction[6].

For air transport:

i) The primary receptacle or secondary packaging must be capable of withstanding, without leakage, an internal pressure of 95 kPa. The primary receptacle or secondary packaging must also be capable of withstanding temperatures in the range of –40°C to +55°C;

ii) For liquids: the net quantity of infectious substances per one P620 box shall not exceed 50 ml for transport in cargo space of a passenger aircraft; and must not contain more than 4 litres (contain multiple primary receptacles totalling more than 4 litres) for transport on a cargo only aircraft;

iii) For solids: the net quantity of infectious substances per one P620 box shall not exceed 50 g for transport in cargo space of a passenger aircraft, and must not contain more than 4 kg (even if containing multiple primary receptacles totalling more than 4 kg) for transport on a cargo only aircraft. This quantity limit doesn't apply for animal parts, organs and whole carcasses.

iv) The three triple packaging principle has to be adopted accordingly using appropriate packaging systems;

v) The entire package must have been tested and complies with Packing Instruction P620.

For further information on marking and labelling of the Category A shipment package, see P620 Packing Instruction for UN Nos 2814 and 2900[6]

3. Category B

Category B must be transported in a packaging that complies with the requirements of packing instruction P650. The approval of the box by the government is not required, thus UN specification marking is not required.

6 Page 81 at: http://www.unece.org/fileadmin/DAM/trans/danger/publi/unrec/rev20/Rev20e_Vol2.pdf

Marking is as follows:

i) Packages should be clearly labelled with the delivery address and sender's details to guarantee safe delivery in time at the correct destination.

ii) Label with the *proper shipping name* in letters at least 6 mm high: "BIOLOGICAL SUBSTANCE, CATEGORY B" (Figure 2)

iii) In addition to the proper shipping name, the mark shown below (UN3373 in diamond) is used for shipments of Category B substances. The UN3373 mark must always be visible on the outer packaging.

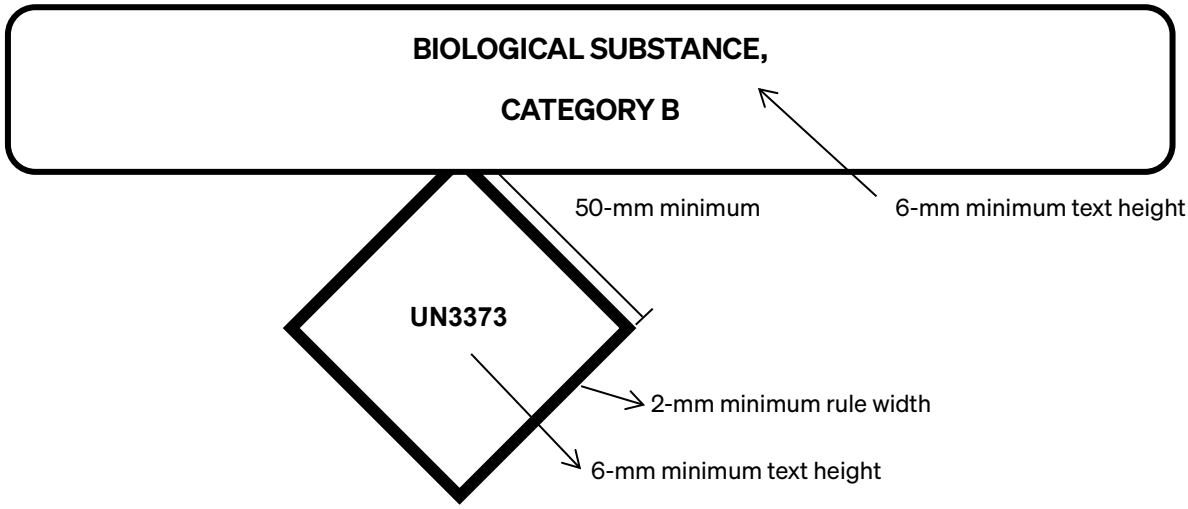

Fig. 2. UN3373 mark for the transport of Category B substances.

Additional requirements do apply as for category A for international shipment and air transport. One of the main differences between P650 and P620 is the reduced drop-test to 1.2 meters (4 feet).

For air transport:

i) The primary receptacle or secondary packaging must be capable of withstanding, without leakage, an internal pressure of 95 kPa. The primary receptacle or secondary packaging must also be capable of withstanding temperatures in the range of –40°C to +55°C;

ii) For liquids: no primary receptacle shall exceed 1 litre and the outer packaging must not contain more than 4 litres (contain multiple primary receptacles totalling more than 4 litres);

iii) For solids: the outer packaging must not contain more than 4 kg. This restriction doesn't apply for animal parts, organs and whole carcasses.

The exact details can be found in P650 Packing Instruction for UN No. 3373[7].

4. Exempt specimens

Biological materials for which there is a minimal likelihood that pathogens are present are not subject to regulation if the specimen is carried in a packaging which will prevent any leakage and which is marked with the words "Exempt animal specimens", as appropriate. The triple packaging system must still be applied.

5. Biological materials not subject to Dangerous Goods Regulations

This exemption refers to biological materials that do not contain infectious substances and are therefore not subject to dangerous goods regulations (such as class 6.2) and any packaging requirements*, unless they meet the criteria for inclusion in another class* (*such as class 9*).

7 Page 82 at: http://www.unece.org/fileadmin/DAM/trans/danger/publi/unrec/rev20/Rev20e_Vol2.pdf

Note: There may be specific regulations in place in some countries for the shipment, export or import of nucleic acids.

6. Overpack

"Overpack" is the term used when one or more packages are combined to form one unit and sent to the same destination by a single shipper. When refrigerants are used to protect contents, the overpacks may comprise insulated vessels or flasks. Whenever an overpack is used, the required marks and labels shown on the outer packaging must be repeated on the outermost layer of the overpack, except for the UN specification marking on P620. This requirement applies to all infectious substances including Categories A and B. Overpacks are also required to be marked with the word "overpack".

Combining different categories of infectious substance in a same overpack is permissible however in this case outer labelling should indicate the highest category included in the package.

7. Cold chain transportation

Refrigerants may be used to stabilise specimens during transport.

Ice, ice packs or dry ice shall be placed outside the secondary receptacle. Wet ice shall be placed in a leak-proof container; the outer packaging or overpack shall also be leak-proof.

Dry ice (solid carbon dioxide) must not be placed inside the primary or secondary receptacle because of the risk of explosion. A specially designed insulated packaging may be used to contain dry ice, typically a polystyrene or waxed-treated cardboard box to prevent leakage and maintain temperature. The packaging must permit the release of carbon dioxide gas if dry ice is used and the package (the outer packaging or the overpack) shall be marked "UN 1845" and "Carbon dioxide, solid as coolant" or "Dry ice as coolant" and the weight of the dry ice in Kilograms should also be indicated on the labelling. The package must also bear the Class 9 – Miscellaneous hazard label.

The secondary receptacle shall be secured within the outer package to maintain the original orientation of the inner packages after the refrigerant has melted or dissipated.

If liquid nitrogen is used as a refrigerant, additional requirements have to be followed according to the relevant regulations for dangerous goods (Division 2.2, UN 1977). Information on Dry Shipper is available in p19 of WHO Guidance on regulations for the transport of infectious substances 2017–2018[8].

D. ADDITIONAL CONSIDERATIONS

In addition to the transport regulations described above, other international agreements might be applicable.

1. CITES

The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) is an international agreement between governments with the aim to ensure that international trade in specimens of wild animals and plants does not threaten their survival. The Convention is in effect in 183 Parties (including one economic integration organisation, the European Union).

Some specimens to be transported from one country to another may be derived from species covered by CITES (roughly 5,600 animal species and 30,000 plant species). Depending on the classification of the species in one of the three Appendices of the Convention and the movement involved, a CITES export permit, both an export and import permit, or re-export certificates may be required. The appropriate documents must be obtained from National CITES Management Authorities. Simplified procedures for the issuance of permits and certificates exist to facilitate and expedite trade in biological specimens from CITES-listed species.

8 http://www.who.int/ihr/publications/WHO-WHE-CPI-2017.8/en/

There may be some variation from one country to another in their CITES trade requirements (some countries take stricter domestic measures and some countries have added additional species requirements for permits in addition to the CITES lists), therefore It is always advisable to check the national legislation that applies.

Further information on CITES: https://cites.org

2. Nagoya protocol and access and benefit-sharing

"Fair and equitable sharing of benefits arising from the utilisation of genetic resources" (Access and Benefit Sharing, or ABS) is one of the three objectives of the Convention on Biodiveristy (CBD). The CBD confirms that States have sovereign rights over their genetic resources, including animals, plants, fungi and microorganisms. Consequently States may choose to regulate access to these, requiring researchers both within and outside their borders to seek permission. Permission (*Prior Informed Consent* or PIC) will be the responsibility of the State and maybe other stakeholders, and the conditions for sharing benefits (*Mutually Agreed Terms* or MAT) may be agreed with a range of actors, including laboratories.

In 2014 the *Nagoya Protocol on Access and Benefit Sharing* (NP) was agreed by the Parties of the CBD. Nagoya Protocol requirements have been implemented in a large number of countries. This obliges the Parties to take compliance measures and monitor researchers and others utilising genetic resources (accessed from other Parties) within their jurisdiction. Biological material containing genetic resources as defined under the CBD may be subject to national Access and Benefit-Sharing (ABS) legislation in both the country where it is sourced and the country where it is sent. This may include compliance with the NP if both countries are Party to the NP. To discover whether this is the case, consult the ABS Clearing House (https://absch.cbd.int/), and ask the National Focal Point of both countries (contact details on ABS Clearing House). If the source country has ABS legislation it may be necessary to seek a permit (Prior Informed Consent and Mutually Agreed Terms) prior to international transport of the material.

Benefits may be monetary or non-monetary. "Utilisation of genetic resources" is defined by the CBD as "means to conduct research and development of the genetic and/or biochemical composition of genetic resources, including through the application of biotechnology as defined in Article 2 of the Convention". Consequently many activities carried out by WOAH Members and their constituents may be classified as ABS.

Compliance will require researchers to produce documentary evidence that genetic resources were accessed with appropriate PIC and MAT, and declaring the type of utilisation being undertaken. This information will be transmitted to the provider country to check if the information accords with their records. There is no exemption for organisms of veterinary importance from ABS provisions in the NP, but countries where they are being accessed may choose to make this distinction and exemption.

Article 8 of the Nagoya Protocol states "*In the development and implementation of its access and benefit-sharing legislation or regulatory requirements, each Party shall: … (b) Pay due regard to cases of present or imminent emergencies that threaten or damage human, animal or plant health, as determined nationally or internationally. Parties may take into consideration the need for expeditious access to genetic resources and expeditious fair and equitable sharing of benefits arising out of the use of such genetic resources, including access to affordable treatments by those in need, especially in developing countries*;". However, this is not required and counties may choose to take no action. In addition, there is a 90-day grace period allowed to complete required documents after transport of the biological material.

If the research or diagnostic work on biological material of veterinary concern is considered 'utilisation' by the country (Party) in which it takes place the researcher will be required to provide information, including:

i) The Internationally Recognised Certificate of Compliance (number) from the ABS Clearing House, if available; or
   a) ABS Permit reference
   b) Evidence of Prior Informed Consent
   c) Evidence of Mutually Agreed Terms
   d) The entity to whom PIC and MAT was granted

ii) The Provider Country

iii) Date and place of access

iv) Description of the Genetic Resources

This information should be included in the documents with the transported biological material.

Although this documentation is only required if both providing country and recipient country are Party to the Nagoya Protocol the provider may have Access and Benefit-Sharing legislation even if not a Party. This should be respected and any documentation required, including permits, Prior Informed Consent and Mutually Agreed Terms, acquired and dispatched with the material.

Further information can be found on:

i) The ABS Clearing House - https://absch.cbd.int/

ii) The CBD Website - https://www.cbd.int/abs/default.shtml

MOST RECENT UPDATES ADOPTED IN 2018.

APPENDIX 1.1.3.1.

DEFINITIONS

The following definitions are for the purposes of this chapter only. For general definitions please see the Glossary.

- **Biological products**

Biological products are those products derived from living organisms which are manufactured and distributed in accordance with the requirements of appropriate national authorities, which may have special licensing requirements, and are used either for prevention, treatment, or diagnosis of disease in humans or animals, or for development, experimental or investigational purposes related thereto. They include, but are not limited to, finished or unfinished products such as vaccines.

- **Cultures**

Cultures are the result of a process by which pathogens are intentionally propagated. This definition does not include human or animal patient specimens as defined below.

- **Infectious substances**

For the purposes of transport, infectious substances are defined as substances which are known or are reasonably expected to contain pathogens. Pathogens are defined as microorganisms (including bacteria, viruses, parasites, fungi) and other agents such as prions, which can cause disease in humans or animals. Infectious substances are further classified according to risk into two categories.

- **Genetically modified microorganisms (GMMOs) and organisms (GMOs)**

Genetically modified microorganisms not meeting the definition of infectious substance are classified in Class 9 (Miscellaneous dangerous substances and articles, including environmentally hazardous substances). GMMOs and GMOs are not subject to dangerous goods regulations when authorised for use by the competent authorities of the countries of origin, transit and destination. Genetically modified live animals shall be transported under terms and conditions of the competent authorities of the countries of origin and destination. DNA, RNA or plasmids are not considered as GMMO and not subject to dangerous goods regulations.

- **Medical or clinical wastes**

Medical or clinical wastes are wastes derived from the veterinary treatment of animals, the medical treatment of humans or from bio-research.

- **Patient specimens**

Patient specimens are those, collected directly from humans or animals, including, but not limited to, excreta, secreta, blood and its components, tissue and tissue fluid swabs, and body parts being transported for purposes such as research, diagnosis, investigational activities, disease treatment and prevention.

Title and name:
Address:

I. OBJECTIVE AND PURPOSE

[Insert a short statement about the objectives and intended purpose of the agreement and background to the parties to the agreement.]

II. DEFINITIONS

Provider
Organisation providing the *original material*. The name and address of this party will be specified in the first page of this MTA.

Provider scientist
The name and address of this party will be specified in an implementing letter.

Recipient
Organisation receiving the *original material*. The name and address of this party will be specified in an implementing letter.

Recipient scientist
The name and address of this party will be specified in an implementing letter.

Original material
The description of the material being transferred will be specified in an implementing letter.

Material
Original material, *progeny*, and *unmodified derivatives*. The *material* shall not include: (a) *modifications*, or (b) other substances created by the *recipient* through the use of the *material* which are not *modifications*, *progeny*, or *unmodified derivatives*.

Progeny
Unmodified descendant from the *material*, such as virus from virus, cell from cell, or organism from organism.

Unmodified derivatives
Substances created by the *recipient* which constitute an unmodified functional subunit or product expressed by the *original material*. Some examples include: subclones of unmodified cell lines, purified or fractionated subsets of the *original material*, proteins expressed by DNA/RNA supplied by the *provider*, or monoclonal antibodies secreted by a hybridoma cell line.

Modifications
Substances created by the *recipient* which contain/incorporate the *material*.

Commercial purposes
The sale, lease, license, or other transfer of the *material* or *modifications* to a for-profit organisation. *Commercial purposes* shall also include uses of the *material* or *modifications* by any organisation, including *recipient*, to perform contract research, to screen compound libraries, to produce or manufacture products for general sale, or to conduct research activities that result in any sale, lease, license, or transfer of the *material* or *modifications* to a for-profit organisation. However, industrially sponsored academic research shall not be considered a use of the *material* or *modifications* for *commercial purposes* per se, unless any of the above conditions of this definition are met.

Non-profit organisation(s)
A university or other institution of higher education or an organisation exempt from taxation or any nonprofit scientific or educational organisation qualified under a state nonprofit organisation statute. As used herein, the term also includes government agencies.

Agreement
Material Transfer Agreement (MTA)

III. TERMS AND CONDITIONS OF THIS AGREEMENT

Ownership
The *provider* retains ownership of the *material*, including any *material* contained or incorporated in *modifications*.

The *recipient* retains ownership of:

(a) *modifications* (except that, the *provider* retains ownership rights to the *material* included therein);

(b) those substances created through the use of the *material* or *modifications*, but which are not *progeny*, *unmodified derivatives* or *modifications* (i.e., do not contain the *original material*, *progeny*, *unmodified derivatives*). If either 2 (a) or 2 (b) results from the collaborative efforts of the *provider* and the *recipient*, joint ownership may be negotiated.

Non-commercial use
The *recipient* and the *recipient scientist* agree that the *material* is to be used solely for either teaching, non-commercial research or academic research purposes. In this Agreement, non-commercial research purpose and academic research purpose mean that the *material* cannot be used for *commercial purposes*, and the *recipient* may not exploit commercially the results, inventions, discoveries or know-how which incorporates the *materials* for its own benefit nor for a third party, without the consent of the *provider*.

Ownership of the results, inventions, discoveries or know-how generated by the *recipient* using the *material* shall rest with the *recipient*. Nevertheless, any results, inventions, discoveries or know-how which contain or incorporate the *material*, generated by the *recipient* using the *material* ("*modifications*") shall be jointly owned by the *provider* and the *recipient*. However, both the *provider* and the *recipient* agree that should the *recipient* having completed work under this MTA wish to use the *material* or *modifications* for commercial purposes it will be necessary for the *recipient* to negotiate the terms of a license Agreement with the *provider*, No right are given, implied or intended by this Agreement or the material transfer other than those explicitly stated in this Agreement.

Distribution to third parties
This *material* should be considered a property of the *provider*. The *recipient* therefore agrees to retain control over this material, and further agrees not to transfer the *material* to third parties or to personnel of the *recipient* not working under the supervision of the *recipient scientist*. The *recipient* agrees to refer to the *provider* any request for the *material* from anyone other than those persons working under the *recipient scientist*'s direct supervision. The *provider* reserves the right to distribute the *material* to others and to use it for its own purposes.

The *recipient* shall have the right, without restrictions, to distribute substances created by the *recipient* through the use of the *original material* only if those substances are not *progeny*, *unmodified derivatives*, or *modifications*.

Under a separate agreement at least as protective of the *provider*'s rights, the *recipient* may distribute *modifications* to *non-profit organisation(s)* for non-commercial research purposes and academic research purposes only, subject to prior written notice to the *provider*.

Confidentiality
The *recipient* agrees to treat the *materials* as it would treat its own confidential and proprietary information and at least no less than a reasonable degree of care, and to take all reasonable precautions to prevent unauthorised disclosure to any third party of the *material* which it receives hereunder. The *provider* agrees to keep confidential that the *recipient* is using the *material*.

Publications
This Agreement shall not be interpreted to prevent or delay publication of research findings resulting from the use of the *material* or the *modifications*. The *recipient scientist* agrees to provide appropriate acknowledgement of the source of the *material* in all publications.

Material use liability
The *material* is provided as a service to the research community at large. It is provided without warranty of merchantability or fitness for a particular purpose or any other warranty, express or implied. No indemnification for any damages is intended or provided under this Agreement. Each party should accept liability for their own actions. The parties make no express or implied warranty as to any matter whatsoever, including the conditions of the research or any invention or product, whether tangible or intangible, made, or developed under this Agreement, or the ownership, merchantability, or fitness for a particular purpose of the research or any invention or product. The

parties further make no warranty that the use of any invention or other intellectual property or product contributed, made or developed under this Agreement will not infringe any patent or other intellectual property right. In no event, will any party be liable to any other party for compensatory, punitive, exemplary or consequential damages.

Misuse, dual use and biosafety
The *recipient* accepts full responsibility for the safety of the research and warrants that the research will be performed in accordance with all local or national laws, rules and regulations. In particular, this *material* will only be used for research purposes by the *recipient* in its laboratory under suitable containment conditions.

Under the terms of this Agreement, the *material* may not be used in human beings.

Termination of the Agreement
The term of this Agreement is 2 years as of the effective date of termination, unless an extension is mutually agreed by the *provider* and the *recipient*. At the end of this term, the Agreement shall automatically terminate. Upon the effective date of termination, or if requested, the deferred effective date of termination, the *recipient* will discontinue its use of the *material* and will, upon direction of the *provider*, return or destroy any remaining *material*. The cost of return or destruction will be taken by the *recipient*.

Dispute
Any dispute arising under this Agreement instituted against the *recipient* by the *provider* shall be brought in the court of the *recipient*'s country of domicile. Any claims and proceedings against the *provider* by the *recipient* shall be brought in the courts of the *provider*'s country of domicile.

Modification of the Agreement and signatures
This agreement may not be modified, in whole or in part, except by the written consent of both parties. If any provision of this Agreement may be signed in counterpart, and by the parties hereto or separate counterparts, each of which shall be deemed an original.

This Agreement is effective when signed by all parties. The parties executing it certify that their respective organisations have accepted the terms of this Agreement, and further agree to be bound by the terms, for the transfer specified above.

Recipient responsibility
The Recipient undertakes to use the Material in full compliance with any national and international applicable law, including any disposition and guidelines regarding health and scientific research. In particular, the Material having intrinsic health risk shall be handled in full respect of the specific law and in compliance with all the necessary precautions.

The Recipient represents that within its laboratories:

- Access to the Material, Progeny and Modification will be restricted to personnel capable and qualified to safely handle those substances, using appropriate containment;
- Recipient shall use the utmost precaution to minimise any risk of harm to persons and property and to safeguard them from theft or misuse.

The Recipient also acknowledges that in no event the Material applies directly or indirectly to humans.

The Recipient assumes all liability for any and all third party damages and claims arising out of or relating to this Agreement, including the receipt, use, handling, storage, conservation of the Material. To the extent permitted by applicable law, the Recipient agrees to indemnify, defend and hold harmless the provider against all third party claims, losses, expenses and damages, including reasonable attorney's fees.

The provider shall have no liability towards the Recipient or its employees in the event that the Material and/or Derivatives infringe any intellectual property rights of third parties. The provider makes no warranties for the absence of any third party industrial property rights on the Material.

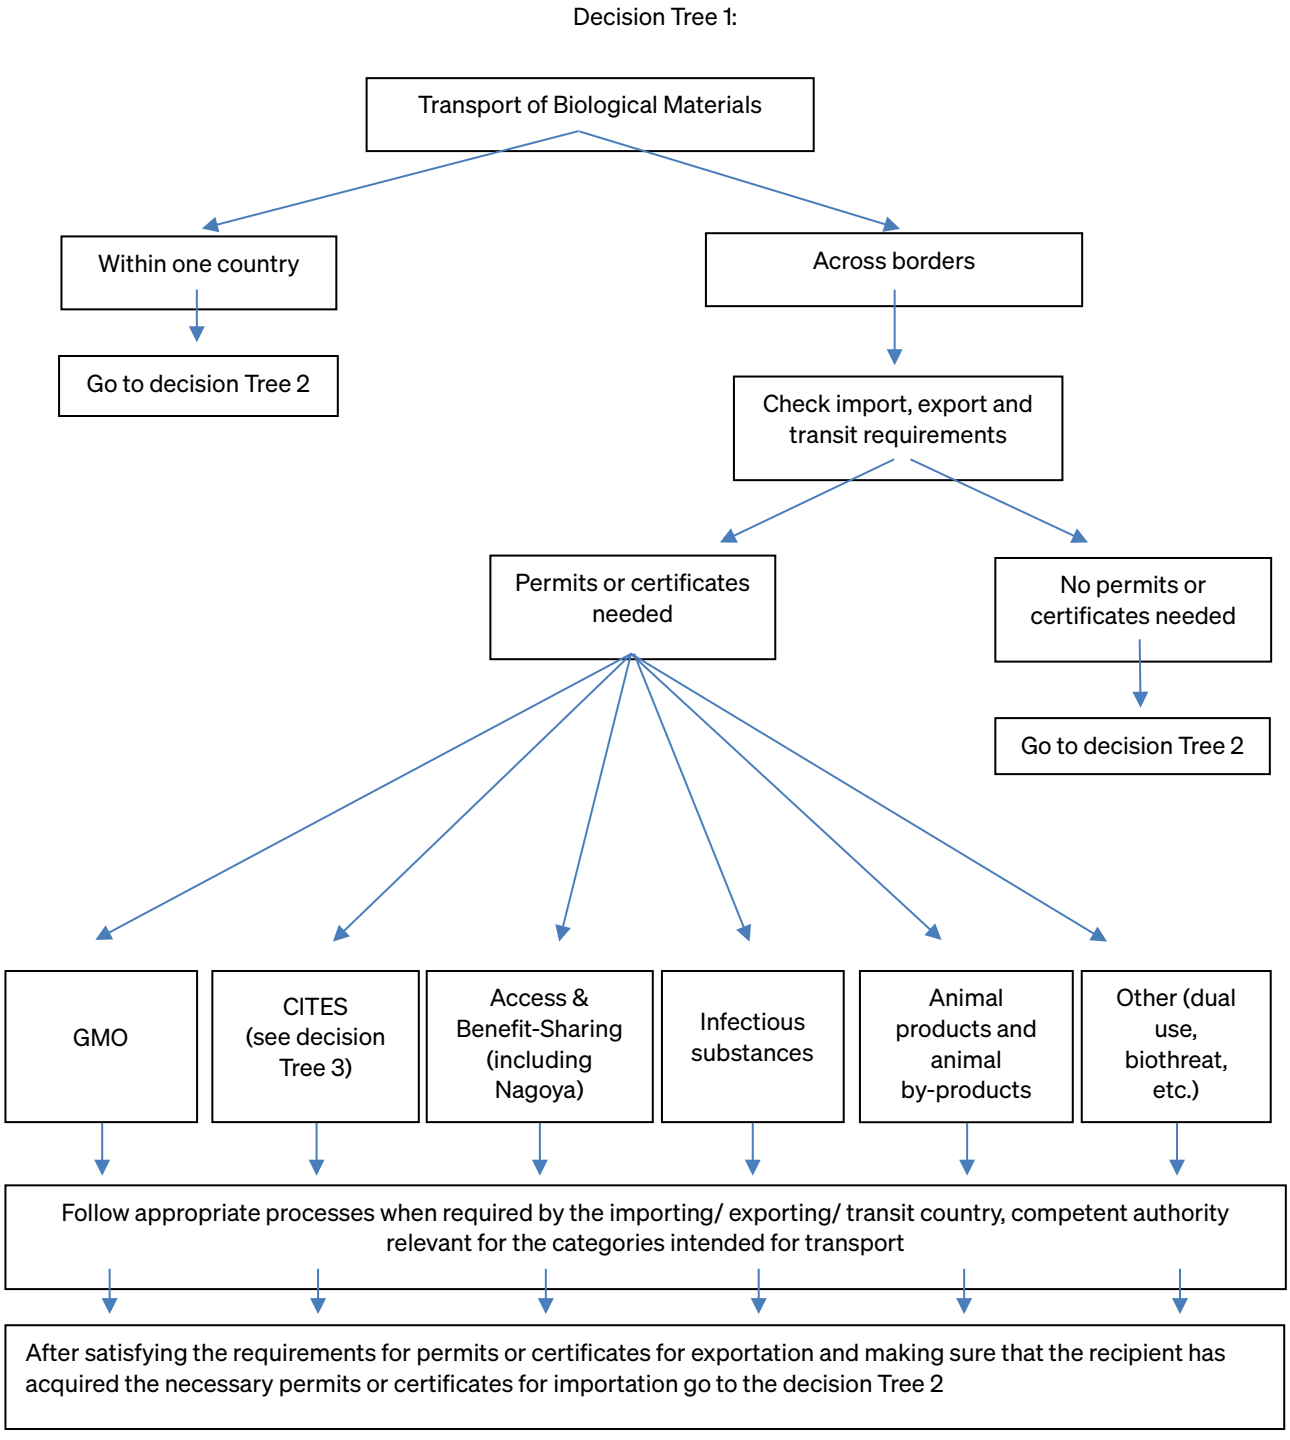
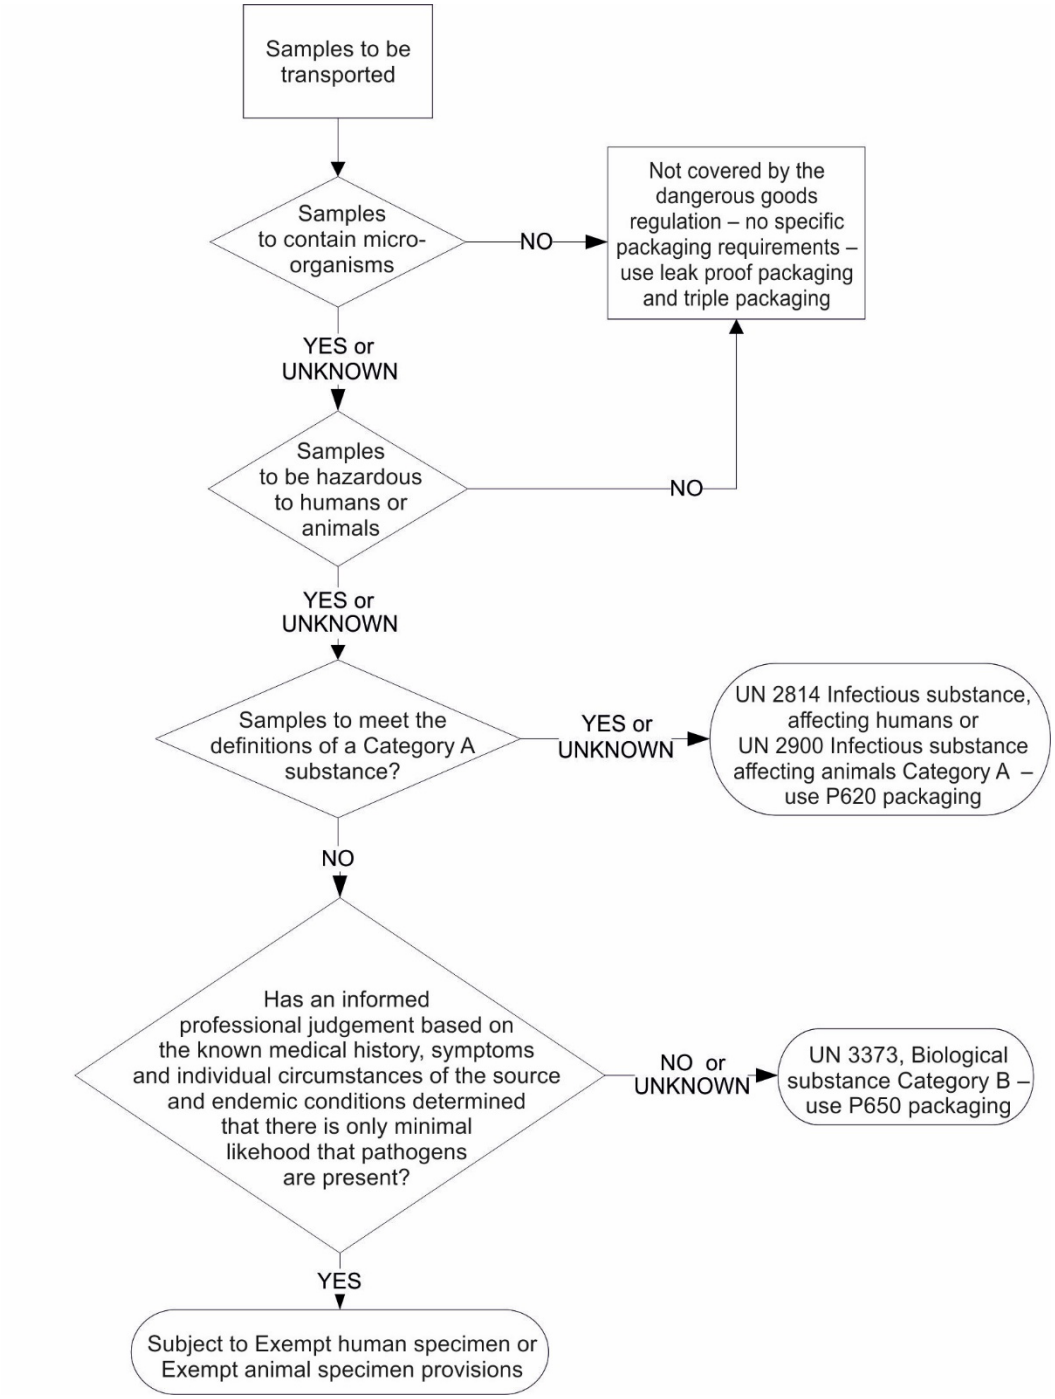
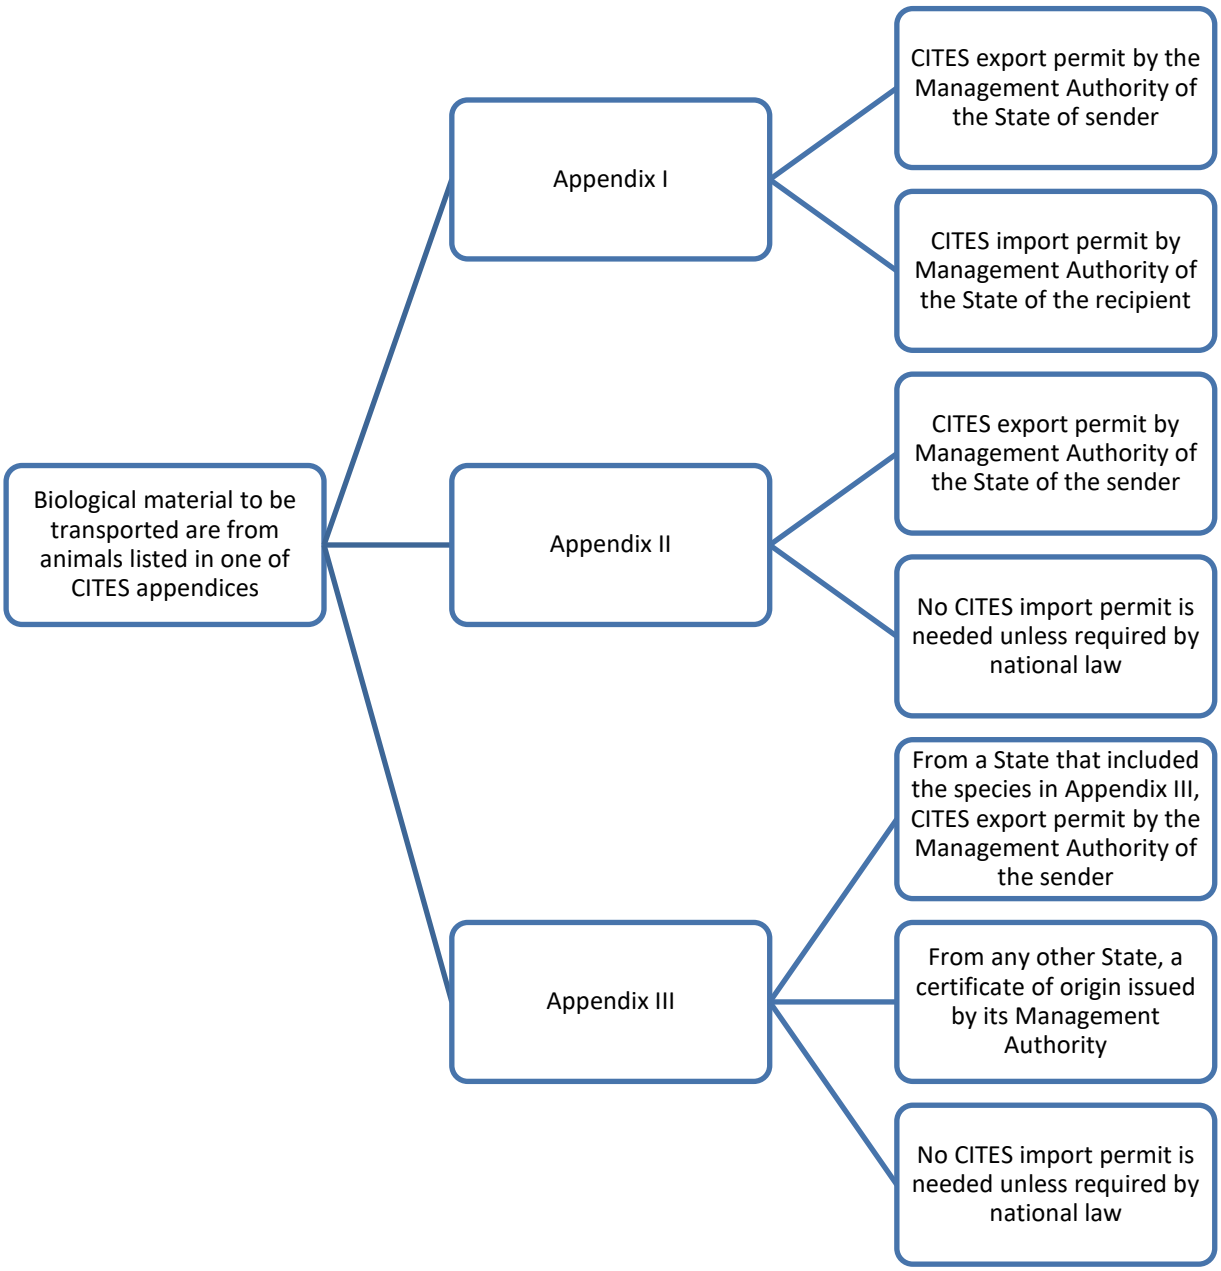
DECISION TREES FOR THE TRANSPORT REQUIREMENTS OF BIOLOGICAL MATERIALS



Decision Tree 2



Decision Tree 3



CHAPTER 1.1.4.

BIOSAFETY AND BIOSECURITY: STANDARD FOR MANAGING BIOLOGICAL RISK IN THE VETERINARY LABORATORY AND ANIMAL FACILITIES

INTRODUCTION

Chapter 1.1.1 Management of veterinary diagnostic laboratories *outlines the overall requirements and responsibilities to be addressed in the management of veterinary laboratories, of which management of the biological risks associated with the operation of a laboratory is an important aspect. This chapter outlines the principles on which the specific management of biological risks associated with veterinary laboratories and experimental animal handling facilities should be based. The terminology is aligned with the WOAH nomenclature for risk analysis, including the four components, namely hazard identification, risk assessment, risk management and risk communication, used in Chapter 2.1* Import Risk Analysis *of both the WOAH* Terrestrial Animal Health Code and *WOAH* Aquatic Animal Health Code*. In this way the process is consistent with and standardised against risk analysis processes already used by WOAH Members.*

Adoption of the risk analysis approach to management of biological risks for biosafety and biosecurity in veterinary laboratories and animal facilities provides Members with a means of tailoring their relevant national animal health policies and procedures regarding their laboratories to their particular circumstances and priorities. The biological risk management approach gives countries a mechanism to protect their human and animal populations from inadvertent or intentional release of or exposure to animal pathogens in an evidence-based, transparent, economically viable and sustainable manner. The approach is applicable in all countries from technologically advanced to in-transition or resource-limited countries.

The risk analysis approach moves towards a comprehensive biological risk management framework that is science-based and specific to an individual country and laboratory's circumstances. The process could accommodate the assigning of pathogens to risk groups relevant to the country and the subsequent restriction of the associated work to laboratory facilities defined by containment levels tailored to the types of risk identified if this suits an individual country's requirements as identified by its biological risk analysis. This chapter and the associated Chapter 2.1.3 Managing biorisk: examples of aligning risk management strategies with assessed biorisks *provide the framework for implementation of the risk management approach.*

Veterinary laboratories and animal facilities routinely handle biological materials that may constitute or contain infectious agents and toxins that may cause adverse animal or public health and economic effects due to uncontrolled release inside or outside the laboratory. Laboratory and animal facilities managers are responsible for providing a management system that ensures safe and secure handling, storage, and transport of these biological materials (a biological risk management system). This is needed not only to protect laboratory workers from inadvertent exposures and infection, but also to protect the local and regional animal populations, human populations, and environment from accidental or intentional release and spread of biological agents and toxins from laboratories. These considerations should also apply to animals and potential arthropod vectors that are handled in veterinary laboratories and animal facilities. The term "biological material" is used throughout this chapter to include all potential sources of biological risk for which laboratory management may be responsible. To classify the potential biological risk posed by the presence and handling of a particular biological material, laboratory managers should apply a systematic and evidence-based approach.

Biological risk analysis is the process of identifying and characterising health, safety, and security risks, followed by implementing, measuring the effectiveness of, and communicating the control measures used to reduce those risks to acceptable levels. Risk analysis has been used effectively by individuals in business and finance, engineering, energy, and health industries to characterise and control inherent risks associated with their business practices. This chapter focuses on biological-related risks, recognising that additional health and safety concerns exist, and should be controlled within the laboratory environment, such as radiation exposures, chemical burns, or liquid nitrogen hazards. A laboratory biological risk management system includes the policies, responsibilities, and operational procedures used to support biological risk analysis and the resulting biosafety and laboratory biosecurity measures implemented to manage laboratory biological risks.

Additional definitions and further explanation of the risk analysis principles and associated laboratory biological risk management system approach presented in this chapter can be found in the WOAH Handbook on Import Risk Analysis for Animals and Animal Products *and in the European Committee for Standardization* (*CEN*) *Workshop Agreement on Laboratory Biorisk Management. Following the overview presented in this chapter, a general guide for performing a risk analysis is included in Appendix 1.1.4.1. The types of biological hazards to be considered, the associated risks and the types of management strategies to be considered are provided in a table in Appendix 1.1.4.2. Chapter 2.1.3 contains worked examples based on hypothetical scenarios of how the checklist can be worked through for specific infectious hazards.*

A. LABORATORY BIOSAFETY AND BIOSECURITY BACKGROUND

As outlined in Chapter 1.1.1 *Management of Veterinary Diagnostic Laboratories*, it is a standard for Members having such facilities that they be managed within the context of a formally stated animal health policy that indicates clearly the purposes for which laboratory services are required. This animal health policy typically includes specific mention of the disease agents for which a diagnostic or research capability is required and allows for the subsequent design and development of a laboratory capability that is fit for purpose. The design of the laboratory capability will guide decisions regarding the use or avoidance of particular direct and indirect laboratory test methods that may involve the handling, propagation, and storage of particular infectious agents or toxins in the laboratory. This process should be expected to result in a list of the biological materials, including each specific infectious agent that will be held by the laboratory.

Biological risk assessments are undertaken to inform and determine the policy and procedures that in turn give confidence that the laboratory procedures for each of the biological materials handled by the laboratory pose negligible danger to a country's animal and human populations. The assessments of biological risk are usually taken at a national or jurisdictional level and may lead to national or jurisdictional standards or regulations for biological risk management that are followed by all veterinary laboratories and animal handling facilities in that country or jurisdiction. Agencies and laboratories responsible for biological risk analysis may make use of data, information and guidance available in published technical documents such as specific chapters of the WOAH *Terrestrial Animal Health Code*, the *Aquatic Animal Health Code* and this *Terrestrial Manual* as well as publications from other internationally recognised bodies and organisations.

It is the intention of this chapter to provide countries and laboratories with a process that can be applied when developing standards, policies and procedures appropriate to their particular circumstances. It is additionally a requirement that the process be transparent to other Members that may have a legitimate interest in the effectiveness of the management of laboratory biological risks in the particular country. Although this chapter is applicable to veterinary laboratories and animal handling facilities, it is noted that in the international context, issues that have an impact on public health are also subject to binding international agreement. Consequently, the veterinary biological risk analysis process must deliver outcomes in support of the particular country's obligations regarding zoonotic diseases, such as under the World Health Organization (WHO) International Health Regulations (IHR) (WHO, 2005). For countries in the process of developing their national standard, this chapter provides guidance for identifying and assessing the country's animal health risks and related laboratory management strategies.

Laboratory biosafety describes the principles and practices for the prevention of unintentional release of or accidental exposure to biological agents and toxins. Laboratory biosecurity describes the physical control of biological agents and toxins within laboratories, in order to prevent their loss, theft, misuse, unauthorised access or intentional unauthorised release. These and other terms are defined in the Glossary of this *Terrestrial Manual.*

Laboratory risk assessments are used to identify the specific biosafety and biosecurity measures needed to contain and work safely with specific biological agents and toxins in a laboratory or animal facility. The common practice of linking a biological agent to a specific level of biocontainment arises from the concept of identifying biological agents and toxins as *biohazards* and classifying the individual agents into one of four risk groups based on the potential to cause disease in an individual and in a community. The criteria used in risk group classification schemes, which although similar are not consistent between countries, typically include pathogenicity, mode of transmission, host range, the presence of vectors, existing levels of population immunity, availability of appropriate prophylaxis or treatment, density and movement of the host population, and related environmental factors.

Independent of the biological agent "risk group" classification process, biosafety level designations (alternately termed physical containment levels) were historically developed to characterise laboratories based on a composite of physical design features, facility construction, equipment, operational procedures, and laboratory practices required for working safely with the range of biological agents and toxins that pose varying levels of risk to individuals and to a community. Laboratory facilities have been designated by WHO as: basic – Biosafety Level (BSL) 1 (basic teaching and research); basic – BSL 2 (primary health services, diagnostics, research); containment – BSL 3 (special diagnostics, research); and maximum containment – BSL 4 (dangerous pathogens) (WHO, 2004). The biosafety level classification system has been questioned in that uniform standards and definitions are not used globally, therefore comparison of laboratories using the numerically designated classification schemes of different countries may not be equivalent or representative.

It is critical to note that the classification of specific biological agents into risk groups was never intended to equate directly with similarly designated laboratory biosafety levels; instead, the link between a specific agent and specific individual biosafety measures was intended to be determined by an assessment of biological risk associated with the presence and handling of the individual biological agent and the associated procedures used in the particular facility or environment. It is the individual biosafety and laboratory biosecurity measure or composite of measures, rather than a designated biosafety level, that guides a laboratory in the safe and secure handling of any individual biological agent or toxin. These specific biosafety and biosecurity measures are identified during a *biological risk assessment* which takes into consideration a laboratory's organisation, the facility, and the surrounding environment in which the biological agent or toxin is to be handled. Over time the role of formal risk assessments in selecting appropriate biological risk mitigation measures has been minimised or over-looked in many laboratories, and replaced by generic assignment of biological agents based on their risk group classification into laboratory facilities defined by one of the four biocontainment levels. Such practices do not necessarily lead to appropriate strategies for the informed management of biological risks.

Moreover the expense of building and of maintaining high level containment laboratories can be impractical or prohibitive for some countries, or may simply not provide the most practical and feasible means of managing a specific biological risk. A laboratory-specific biological risk assessment and associated laboratory risk control decisions based on the country or region's animal health strategy, including consideration of endemic disease status, environment, animal movement, trade arrangements, and geopolitical borders, tends to be both more practical and effective.

This chapter defines the terminology and approaches used in biological risk analysis, and in doing so provides a practical approach for countries, jurisdictions and veterinary laboratories to develop, implement, and maintain appropriate biosafety and laboratory biosecurity measures leading to a functional and efficient biological risk management system.

B. BIOLOGICAL RISK ANALYSIS AND BIOLOGICAL RISK MANAGEMENT SYSTEM

Biological risk analysis includes identification of biohazards, a laboratory assessment followed by management of the associated biological risks, and biological risk communication. For veterinary laboratories, biological risk analyses focus on the potential for animal, human, and environmental exposures, including both intentional and unintentional release of biological agents and toxins from the laboratory. It is the laboratory's biological risk management system that ultimately provides laboratory managers, as well as the veterinary authorities of a country or jurisdiction, with a structured process for assessing, reviewing and controlling biological risks.

The laboratory's biological risk management system includes the policies, procedures, and operational components needed for identifying, determining the extent of, managing, and communicating disease and economic risks associated with a specific biological agent in the context of how that agent is handled, manipulated, and maintained in the laboratory.

It is the responsibility of the laboratory to ensure suitable methodologies for the allocation of actions resulting from biological risk assessments, including timelines, responsible persons, and that the associated reporting and approval mechanisms are identified, implemented, and maintained (CEN, 2011). This is accomplished through the development of a risk management policy appropriate to the nature and scale of the facility, activities, and associated biological risks. The policy (or policies) is designed to (a) protect staff, contractors, visitors, the community, surrounding animal populations, and the environment from unintentional or intentional release of or exposure to biological agents and toxins stored or handled within the facility; (b) reduce to acceptable levels laboratory risks that may result in release of or exposure to biological agents by conducting risk assessments of laboratory facilities and work practices, identifying appropriate risk control measures, implementing, and monitoring those measures for effectiveness; and (c) effectively informing and communicating to employees and relevant stakeholders the findings and obligations of the risk management system.

A successful biological risk management system will have clear and unequivocal commitment by laboratory management, who ensure that roles, responsibilities, and authorities related to biological risk management are defined, documented, and communicated to those who manage, perform, and verify work associated with biological agents and toxins in the laboratory. Laboratory management will ensure (a) the provision of adequate resources; (b) prioritisation and communication of biosafety and biosecurity policy; (c) integration of biosafety and biosecurity practices throughout the laboratory; and (d) a robust process of monitoring and evaluation that identifies opportunities for improvement, determines root causes where unsatisfactory situations arise and revises policies and procedures to prevent recurrence. The ongoing verification and continual improvement of a laboratory's effectiveness in managing its risks is a key component of a complete and effective biological risk management system.

Each laboratory should appoint a biological risk management advisor who will report directly to senior laboratory management and have authority to lead the development and implementation of the biological risk management system, be responsible for developing and maintaining documentation for all aspects of the system, and for monitoring the system within the laboratory or facility. The biological risk management advisor is an individual knowledgeable about the laboratory facility, laboratory procedures used, and biological agents and toxins likely to be encountered in the particular laboratory. In smaller laboratories the biological risk management advisor may also have other roles or duties, often quality management or safety management. The designated biological risk management advisor will have the authority delegated from senior management to call for the cessation of work that is not compliant with the laboratory's biological risk policies and procedures.

The key functions of biological risk analysis are: (a) biohazard identification (i.e. what can go wrong?); (b) biological risk assessment (i.e. how likely is the hazardous event to occur and how severe would be the harm?); (c) risk management (i.e. how can those risks be prevented or minimised to acceptable levels?); and (d) risk communication (i.e. how was the risk identified, characterised and controlled?). In addition there is a need for (e) verification with continual improvement (i.e. are the biosafety and laboratory biosecurity measures effective in controlling the biological risk and can they be improved?). The organisational structure, responsibilities, policies, and practices that provide for these activities, comprise a laboratory's biological risk management system. It is important that all relevant regulatory requirements are identified and fulfilled within the biological risk management system. Legal requirements include any national, federal, regional, state, provincial, city and local regulations with which the laboratory is obliged to comply.

1. Biohazard identification

The first step in the risk analysis process is identifying and documenting the potential laboratory biohazard(s). A *biohazard* can be any biological agent, toxin, or associated laboratory or animal facility procedure with the potential for causing harm or damage. During the biohazard identification process, it is necessary to identify biological agent characteristics that make the agent hazardous, and potentially make the agent attractive for malicious use or theft. Although not the focus of this chapter, it should additionally be noted that laboratories must be critically aware of all potential hazards (any source, situation, or act with the potential for causing harm) in the laboratory environment, and not just those that are specifically biological in nature. Examples would include electrical safety, physical safety or radiation hazards, and issues relating to utility failure, poor training, selection of suppliers, etc. that may not appear directly to link themselves to the biological agents and toxins, but that can result in release of a biological agent or toxin, as well as causing other harm.

A laboratory's risk management system should be complete in identifying and managing all hazards, including those outlined hereafter.

1.1. The inventory of biological materials held by and/or manipulated by the laboratory

All biological materials held by the laboratory must be known, recorded and individually addressed in the biological risk assessment process. The specific agents and toxins that a laboratory works with and the associated technical procedures used in that work must be recognised. This will be the primary focus of the biological risk assessment.

1.2. Diagnostic specimens

Veterinary diagnostic centres routinely receive specimens that have been submitted because they are suspect for any of a variety of diseases. While the infectious nature of the specimens is unknown, diagnostic case materials may contain a variety of unknown agents, some of which could be extremely hazardous to human health or pose a significant threat to animal populations. Veterinary diagnostic laboratories have the responsibility to implement appropriate biosafety and laboratory biosecurity measures to minimise the risk of occupational exposure of employees, or of release and spread to the population of pathogens that may be contained within diagnostic specimens. Initial laboratory processing of all unknown diagnostic specimens must be carried out with the assumption that an infectious agent or toxin likely exists in the specimens submitted. Until the specimen has been characterised as non-infectious, it is important that veterinary laboratories take adequate precautions to prevent exposure via percutaneous and mucous membrane routes, and particularly through inhalation and ingestion. Once a specific agent or toxin has been identified by the laboratory, further work is carried out using relevant biocontainment and risk controls.

1.3. Transportation and storage of pathogens

Requirements used for the safe and secure transportation of specimens are given in Chapter 1.1.3 *Transport of biological materials*. Storage of viable agents is a common laboratory and animal facility practice, and therefore a biohazard, in most if not all veterinary laboratories and animal facilities. The risks associated with accidental contact or unauthorised access to biological agents and toxins must be addressed within the storage facility and inventory system. As noted previously, it is an important biosecurity responsibility of veterinary laboratories and animal facilities to identify and to minimise any risk of release of pathogens into human and animal populations, either domestic or wild.

1.4. Physical and chemical hazards

Physical and chemical hazards associated with routine laboratory and animal-use manipulations cannot be ignored during biohazard identification exercises. The laboratory and animal facility must identify these hazards within their facility in order to ensure that their biosafety programmes adequately protect laboratory workers. Examples of hazards routinely found in veterinary laboratories include handling and disposal of glass, needles, and sharp instruments; burns from hot solids, liquids, or from radiation, and burns and asphyxiation risks associated with liquid nitrogen; explosion risks associated with incorrect or non-compatible storage of chemicals; and exposure or repeated exposure (dose–effect) to mutagenic, carcinogenic, and toxic chemicals through respiratory and percutaneous routes.

1.5. Laboratory animals

Work with laboratory animals is also an important laboratory hazard. Laboratory animals can generate large amounts of infectious agent, as well as pose risks associated with the potential for bites, scratches, kicks, and related injury to care-takers and laboratory workers. Expanded information on health and safety in laboratory animal facilities is available (Wood & Smith, 1999).

2. Biological risk assessment

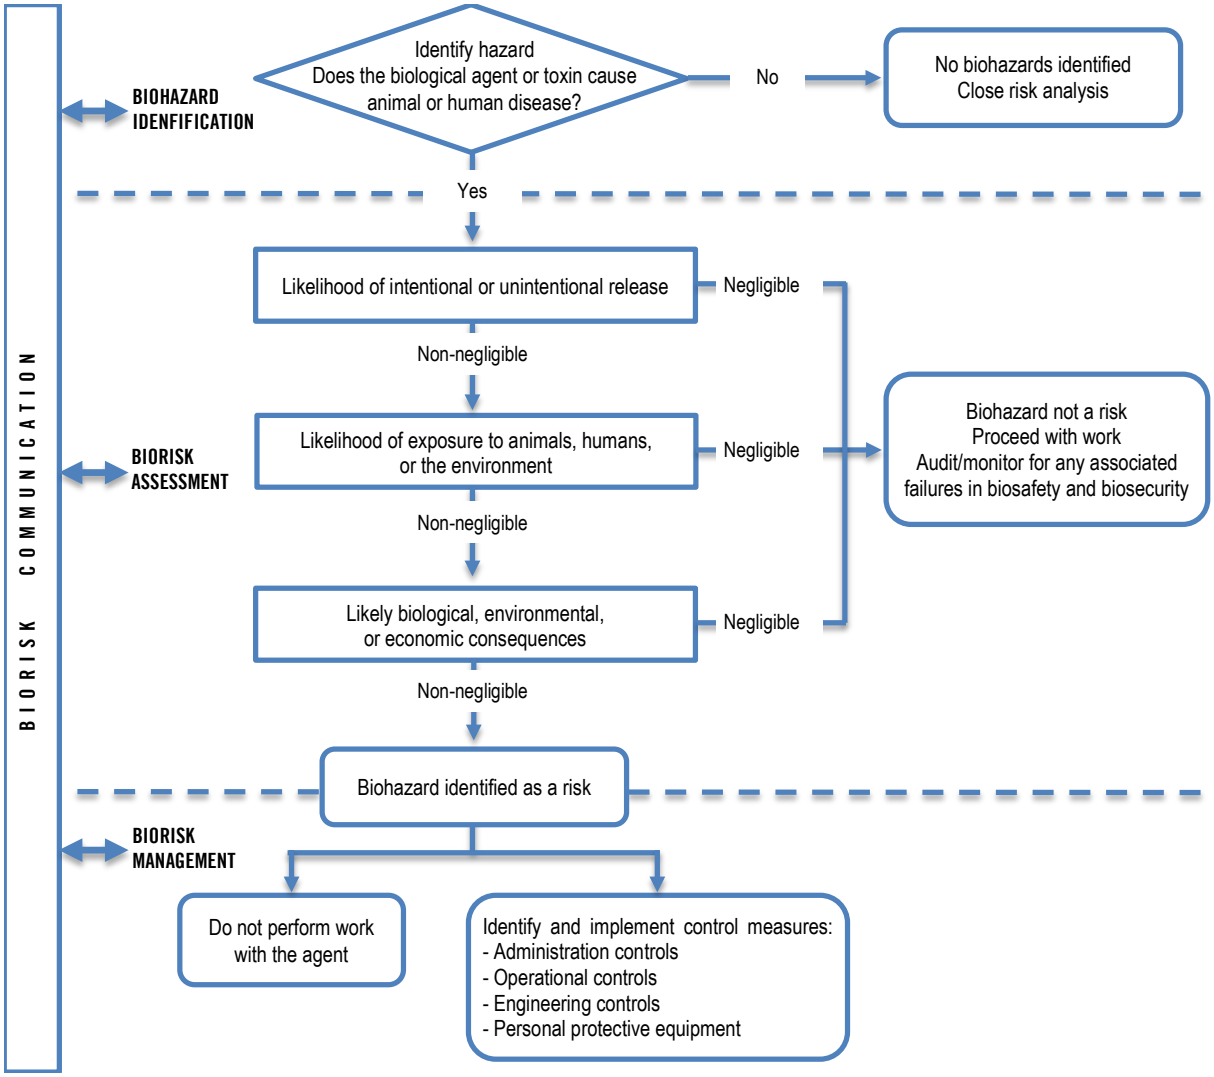
The laboratory's approach to biological risk assessment is a component of the laboratory's risk management policy that defines the scope, nature, and timing of assessments so that the process is proactive rather than reactive. Following identification of the biohazard, the next step in the biological risk assessment process is determining the likelihood and potential severity of consequences or harm associated with that biohazard. Severity (or harm) can be thought of as the biological, environmental, and economic impacts associated with a release of and exposure to the biohazard. The severity of harm associated with animal pathogens and toxins will include human and animal

disease, as well as economic losses associated with local, national, regional, and international restrictions on animal movement and on commerce associated with animals and animal products.

Risk is defined as a combination of the likelihood (probability) of the occurrence and the severity of harm (or consequence); the term biological risk is used where the source of harm is a biological agent or toxin. At this point in the biological risk analysis process (see Flowchart 1), the laboratory with the assistance of their biological risk management advisor, will evaluate the individual facility, human resources, protocols, methodologies and procedures to determine how the biohazard is to be handled and manipulated in their specific circumstances; in addition to assessing the surrounding environment, including identifying susceptible species and the specifics of the biological agent's transmission in order to determine the likelihood and severity of harm (see Appendix 1.1.4.2).

A comprehensive biological risk assessment includes evaluation of both biosafety and laboratory biosecurity practices. Biosafety addresses risks associated with exposure to, or accidental release of the biological material, while laboratory biosecurity addresses potential for theft, misuse, or deliberate release. A comprehensive risk assessment would include consideration of all relevant items that could be at risk for theft or misuse (e.g. electronics, computers, balances) that make the facility a target for theft. It is necessary to consider both biosafety and laboratory biosecurity to ensure that risk control measures implemented are not in conflict with each other and that any one control measure does not compromise others.

Flowchart 1: Biological risk analysis process



Note: The biological risk management process should address all laboratory processes and procedures associated with the specific hazard (biological agent or toxin). The biological risk assessment and biological risk control planning involves a team of individuals who understand the organisational aspects of the laboratory, the biology and pathogenesis of the agent, and the impacts of exposures and accidental or intentional release of the biological agent or toxin.

The biological risk assessment may be quantitative, using mathematical models (WOAH, 2010b), or may be qualitative (CEN, 2011; WOAH, 2010a). For the qualitative biological risk assessment approach discussed here, both likelihood and severity are given a non-numerical score or ranking, which allows a form of "quantifying" the biological risk by using qualitative definitions such as low, moderate, and severe or other non-numerical equivalents. The rankings determined for likelihood and severity of harm will help the laboratory further characterise its biological risks in order to determine the biosafety and laboratory biosecurity control measure(s), the necessary redundancy in controls, and the overall financial investment that will be appropriate to mitigate their specific biological risks.

Resource utilisation and financial investments in biological risk control measures should be proportionate to the biological risks identified in the assessment process ('protect pencils like pencils and diamonds like diamonds'). For example, one outcome of biological risk assessment is a very low likelihood score (e.g. unintentional release of the agent from laboratory containment via some specified process, such as waste treatment), with an extremely high severity score (e.g. release of a non-endemic biological agent with high transmissibility paired with high morbidity or mortality in a susceptible population, loss of trade status, and severe social and economic impacts). In such a case, the laboratory may determine that there are no available mitigation or combination of biosafety and biosecurity measures that would be sufficient to justify handling the biological agent in their facility. The same scenario occurring in a country or region where the agent is endemic may result in the same likelihood ranking, but carry a significantly lower severity ranking. This country could justify an investment for determining and then implementing appropriate biosafety and laboratory biosecurity measures to decrease the likelihood of an unintentional release to an acceptable minimum level.

Where it is determined for a specific biological agent or toxin that there is no severity of harm associated with exposure or release, the biological risk assessment can be concluded.

3. Biological risk management

Where the biological risk assessment identifies unacceptable biological risks, the laboratory is responsible for responding by not handling or storing the specified agent in its facility (elimination of the hazard); by using alternative technical procedures (substitution); or by identifying, implementing and maintaining appropriate biosafety and laboratory biosecurity measures. The response to a biological risk assessment requires documentation of the timelines for action, assignment of responsible persons, and the associated reporting and approvals. Dependent on the outcome of the biological risk assessment (likelihood and severity rankings), the laboratory managers working with the biological risk management advisor will identify which biosafety and biosecurity measure(s) are appropriate and feasible for use within the laboratory or animal facility in order to prevent release of and exposure to the biohazard. The principal routes for exposure and release of biological agents and toxins from laboratory environments include:

i) personnel via surface contamination, infection, or intentional acts allowing release;
ii) aerosol;
iii) liquid and solid waste;
iv) equipment and materials;
v) specimens and reagents;
vi) release via research animals or disease vectors.

To protect biological agents and toxins from unauthorised access or use, the laboratory should additionally consider laboratory security. In general, the components of laboratory security include

i) physical security (e.g. building structure, lockable doors);
ii) personnel (including steps taken to ensure an employee does not pose a safety or security risk);
iii) material control and accountability (inventory control and storage records);
iv) information and information technology security;
v) security of materials during transportation (ensuring the biological material is not subject to theft or diversion during transportation within a facility or between facilities).

In the absence of elimination or substitution as a possible risk control strategy, a strategy that includes administrative, operational, engineering, and personal protective equipment (PPE) controls is used to prevent exposures and accidental or intentional release. The different control approaches are complementary and are used in combination to accomplish appropriate risk reduction. A most basic biosafety and biosecurity programme will ultimately require implementation, at varying degrees, of all the different types of control strategies.

i) *Administrative controls:* qualified and suitable personnel; training and verification of competency of staff in the safe and secure handling of biological agents and toxins, in applicable technical procedures, and in use of PPE and equipment; health and safety programmes; prophylactic health care including vaccinations; emergency response and contingency plans; incident and accident investigation programmes; current biological agents and toxin inventory and inventory management requirements including access, storage, transfer, destruction, and audit; waste management policies; and security policies including facility security, visitor access, personnel security, access to biological agents and toxins; and information security.

ii) *Operational controls:* Standard Operating Procedures for all safety and laboratory biosecurity-relevant processes including Good Microbiological Technique (GMT); disinfection and decontamination practices; transport procedures; general laboratory safety; specimen and reagent handling and storage practices; waste management practices including disinfection and inactivation; emergency exercise drills; and accident/incident reporting, response, and review protocols.

iii) *Engineering controls:* physical features of the facility including ventilation and air-flow, barrier walls and shields, and separation of incompatible activities; equipment and equipment maintenance, calibration and certification; and physical security such as access restrictions, perimeter fences, facility and equipment locks with key control protocols, badge readers, detectors and sensors, or biometric devices. The laboratory must have measures to ensure that all changes to the facility associated with design, operation, and maintenance are documented and that documentation is used to update prior biological risk assessments that may be affected by the change. Engineering controls include the following principles of containment:

    a) *Primary containment layers* are those that enclose the biological agent or toxin within sealed containers or in a Class I, II or III biosafety cabinet. Biological biosafety cabinets must be installed and certified in accordance with the national or manufacturer's standards to ensure effective functioning. Class I cabinets provide personnel and environmental protection. The contents of Class I cabinets are not protected from environmental contamination. Class II cabinets draw a curtain of sterile air over the contents of the cabinet and exhaust through high efficiency particulate air (HEPA) filters in order to protect the contents of the cabinet, personnel, and the environment. Class III cabinets are gas-tight and designed for maximum containment. Class III cabinet engineering (e.g. attached gloves, dunk tanks, etc.) and protocols for use prevent direct contact with hazardous materials and air. In the case of infected animals, the agent is enclosed by physical containment in specially constructed rooms where all wastes are treated and air is filtered.

    b) *Secondary containment layer*s enclose infected materials and individuals working with infected materials within a closed and controlled physical environment that treats solids, fluids, and air using validated filtration and treatment procedures that remove or inactivate live agents.

    c) *Tertiary containment layer*s are those designed to prevent contact between biological agents and susceptible species using appropriate measures that physically restrict exposure to susceptible species.

iv) PPE: body protection (i.e. clothing), hand protection (i.e. gloves), eye protection, and respiratory protection.

Laboratory biosafety should be based on a solid foundation of good microbiological practices in the laboratory to which all laboratory work conforms. The essential requirements for any work with infectious agents or specimens likely to contain infectious agents, however innocuous the material may seem, are as follows:

i) The laboratory should be easy to clean, with surfaces that are impervious to water and resistant to chemicals used in the laboratory. There shall be a hand-wash basin, emergency shower, and eye wash station in each laboratory suite as appropriate for the chemicals and other hazards present. Procedures shall be established for frequent cleaning and disinfection of the work area during and at the end of the work period;

ii) Personnel access to the work area should be restricted (security measures such as controlled access may be necessary with higher risk agents);

iii) Basic PPE such as long-sleeved laboratory coats or gowns, closed-toe footwear, disposable gloves, and safety glasses, shall be worn in the laboratory and removed when leaving the laboratory. Masks, including face shields and oro-nasal respirators may be required as determined by the specific risk assessment;

iv) The laboratory door should be closed when work is in progress, and appropriate access restriction, warning, or biosafety signage clearly visible;

v) While forced ventilation is not a baseline requirement, appropriate ventilation shall be provided for the health and well-being of the workers and as required by risk assessment;

vi) Food (including chewing gum, candy, throat lozenges and cough drops) and drinks shall not be stored or consumed in laboratories; smoking or application of cosmetics shall not take place in the laboratory;

vii) Pipetting shall not be done by mouth;

viii) Care shall be taken to minimise the production of aerosols;

ix) Emergency response plans should be developed to deal with the biohazard of any safety or security incident. Items addressed in the plans should at a minimum include having effective disinfectants and instructions available for cleaning spills, removal and decontamination of contaminated protective clothing, washing of hands, and cleaning and disinfection of bench tops;

x) Used laboratory glassware and other contaminated material shall be appropriately identified (labelled) and stored safely. Materials for disposal shall be transported without spillage in robust containers. Waste material should be autoclaved, incinerated or otherwise decontaminated or inactivated before disposal. Reusable material shall be decontaminated by appropriate means;

xi) No infectious material shall be discarded down laboratory sinks or any other drain;

xii) Any accidents or incidents shall be recorded and reviewed with the biological risk management advisor to assist in continually improving the biological risk management system;

xiii) Workers shall be appropriately trained and verified as competent to perform the tasks assigned.

The risk assessment process is used in determining the appropriate biosafety and laboratory biosecurity controls required for the biohazard (biological agent or toxin) and laboratory or animal facility procedure in question.

4. Risk communication

Laboratory risk communication is a continuation of hazard identification, risk assessment and risk management processes, and is an integral component of incident or outbreak preparedness and response planning. With the understanding that the laboratory's stakeholders and the public are entitled to information that impacts on their own health and the health of their animals, risk communications are designed to inform the laboratory's stakeholders about technical practices and decisions used for handling biohazards and for responding to incidents that may arise from release of and exposure to those biohazards. As laboratories handling animal pathogens and toxins are a critical component of a country or region's veterinary infrastructure, it is critical that the laboratory biological risk management process be thorough, objective, transparent, and clearly communicated (Covello & Allen, 1988).

Effective risk communication should be designed to establish a common understanding among the laboratory and associated stakeholders of the biological risks, biological risk control measures (biosafety and laboratory biosecurity practices implemented), as well as the benefits of working with the identified biohazard. This common understanding not only builds trust, but is critical for effectively responding to potential incidents and enabling impacted individuals and agencies to make informed decisions when working with the laboratory. Risk communication should be provided in a format and language that is tailored to the intended audience, whether policy-makers, disease control authorities, animal care providers, or the public, in order to provide the information in a clear and understandable manner. Effective biological risk communication requires that the complexities of technical language, scientific data, assumptions, and the justification for assumptions used in the biological risk assessment be fully documented.

In general, an initial laboratory biological risk communication is directed toward the appropriate health and disease control authorities and will identify; (1) the biohazard (biological agent or toxin); (2) the benefits to the stakeholder gained by the laboratory working with the biohazard; (3) information indicating that a biological risk analysis was performed and is documented; and (4) information indicating that the laboratory has biosafety and laboratory biosecurity measures in place to mitigate against accidental or intentional release of the biological agent or toxin.

In preparedness for of an accidental or intentional release of the agent, the laboratory should additionally be prepared for incident and incident response communication. Among the documents that the laboratory should generate prior to initiating work with a biohazard are (1) documentation of the roles and responsibilities of individuals involved in drafting, reviewing, approving, and distributing laboratory information and official communications, (2) a contact list containing the names, phone numbers, email addresses or other information as

appropriate for those agencies and individuals to be notified, and (3) an incident response plan in the unlikely event of accidental or intentional release of the biological agent or toxin.

Contact lists should include (1) national, regional, and local disease control authorities (Veterinary Health and Public Health), as appropriate, (2) security authorities, as appropriate, for specific biothreat agents and risks, (3) the responsible physician or occupational health programme to be notified of human health-related agents, biological risks, and at-risk staff, and (4) stakeholders, including potentially impacted laboratory affiliates, e.g. shippers, rendering and waste disposal plants, janitorial staff, non-technical laboratory staff, potentially impacted local animal owners and industries.

5. Verification, corrective actions, and continual improvement

Biological risk management is an ongoing process in which specific biosafety and laboratory biosecurity measures are regularly monitored to ensure they are working as expected. The laboratory facility, management practices, and procedures should also be regularly reviewed to ensure that changes have not altered previously defined risks. Routine audits should be scheduled and conducted to document effectiveness of the implemented biosafety and laboratory biosecurity measures, to identify areas of noncompliance that need to be documented and corrected, and to identify areas for improvement. The process requires that the laboratory verify and document that the control measures implemented (e.g. administrative, operational, engineering, and PPE) effectively mitigate release of and exposure to the targeted biohazards. In a simple example: if during a laboratory assessment, the risk of release was defined as theft due to inadequate physical security, and the biosecurity control used was placement of a lock on the storage freezer, the laboratory administration would want to verify that the control implemented, locking the freezer, had mitigated the risk of theft. Assuming the administration found that the freezer key was kept on an accessible hook near the freezer, the risk of theft had not been adequately controlled and a corrective action would be implemented (e.g. additional or alternative choices of biosecurity control measures, such as implementing added policy and procedures managing access to the freezer key).

It is the responsibility of laboratory managers to continually review and improve the laboratory's effectiveness through the use of documented policy and procedures, training of personnel and verification of competence, self-audit and external audit, where appropriate, corrective and preventive actions, and routine management reviews. The cycle of assessing biological risks, implementing control measures, verifying effectiveness, and correcting any weaknesses follows the same pattern used in well-functioning quality management programmes. Chapter 1.1.5 *Quality management in veterinary testing laboratories* provides an overview of the subject; the CEN *Workshop Agreement on Laboratory Biological Risk Management* details the components of a comprehensive biological risk management system (CEN, 2011).

C. TECHNICAL GUIDANCE AND ASSESSMENT TOOLS

Technical advice and the level of detail needed for selecting individual laboratory and animal facility risk control measures is available through a number of published veterinary health and public health resources, including the WHO Biosafety Manual (WHO, 2004), CDC Biosafety in Microbiological and Biomedical Laboratories (CDC, 2009), Canadian Biosafety Standard and Guidelines (Government of Canada, 2013), Biological agents: Managing the risks in laboratories and healthcare premises (HSE, 2005), Laboratory Biosecurity Handbook (Salerno & Gaudioso, 2007), among others. Assessment tools such as the Food and Agriculture Organization of the United Nations (FAO) LMT (Laboratory Mapping Tool) and the Laboratory Assessment Checklists included in the WHO and CDC Biosafety Manuals, which are used for documenting a laboratory's capabilities and for monitoring compliance with laboratory management standards and good laboratory practices are additionally useful for both external and self-assessments.

D. CONCLUSION

The role of veterinary laboratories is to function as an integral component of a documented national animal health strategy to protect the health and well-being of local, national, regional, and global animal populations and associated commerce as well as protecting public health from biological risks of animal origin. The national animal health strategy will determine the biological materials, and particularly the infectious agents, for which the country's laboratories must maintain a capability.

Within the veterinary laboratory and animal facility environment there will be the inevitable presence and handling of biological materials that can pose biological risks for both animal and human populations. It is therefore of critical

importance that laboratory and animal facility managers ensure that biological risks in their facility are clearly identified, understood, controlled, and communicated to the appropriate stakeholders. It is likely, and recommended, that these risks will be managed within the context of national regulations so that laboratory biological risk management strategies are consistent within countries. The standards communicated in this chapter apply to the development of national standards for managing the biological risks associated with laboratories as much as to the development of biological risk management systems within individual laboratories.

The discipline of biological risk analysis, paired with a comprehensive biological risk management system, allows those responsible to assess and document the laboratory biosafety and biosecurity practices which are used to provide appropriate controls, thus assuring adequate biosafety and laboratory biosecurity. A complete and functioning laboratory biological risk management system will help ensure that the laboratory is in compliance with applicable local, national, regional, and international standards and requirements for biosafety and laboratory biosecurity.

APPENDIX 1.1.4.1.

STEPS IN BIOLOGICAL RISK ANALYSIS

1. Assemble a team for performing the risk assessment. Include individuals with knowledge and understanding of:

    i) The physical and biological properties of the agent or toxin (e.g. the infectious dose, routes of infection, susceptible species, environmental survivability, etc.),

    ii) The laboratory technologies and procedures to be used with the biological agent or toxin, associated technical competence, and laboratory facilities to be used,

    iii) Laboratory biosafety and biosecurity practices,

    iv) Risk analysis principles and practices.

    One team member may serve multiple functions, and qualified individuals from outside of the laboratory performing the analysis may be used. The quality of the risk analysis performed is directly related to the level of knowledge and understanding provided by the team members.

2. Define the scope of the biological risk analysis

    i) Biohazard Identification: identify the target biological agent or toxin. Perform a separate biological risk analysis for each relevant biological agent.

    ii) Define the laboratory environment in which the biological agent or toxin will be used:

        a) Identify technical procedures, methods and processes specifically to be used with the biological agent or toxin being evaluated (e.g. diagnostic specimens or reference materials, amplification in culture, centrifugation, ultrasound, pipetting, freeze–thaw, archival practices, concentrations and volumes of the biological agent or toxin, animal handling, etc.). These items define the laboratory environment relevant to the risk assessment, and document the potential sources of exposure and release from the laboratory environment.

        b) Identify existing laboratory resources, including management and technical competencies (e.g. technical training and proficiency programmes, quality management practices, health and safety management programmes, etc.). These items document existing and potential sources of risk control.

        c) Identify relevant laboratory facilities and associated resources (e.g. facility security, directional air-flow, autoclaves, incinerators, etc.). These items document existing and potential sources of risk control.

3. Develop and initiate the risk communication plan. The documentation and communication of risk analyses must be clear and complete. Because risk analysis supports decision-making where there is uncertainty in predicting events, it is critical that the process be transparent, objective, and clearly presented. It is useful to begin compiling the risk analysis report at the very beginning of the analysis in order to most effectively capture all relevant information, investigation, analysis, and findings.

4. Identify the severity of harm associated with any exposures or release of the biohazard from the laboratory. Severity should identify human health, animal health, and economic harm that would likely result from exposure and from release of the biological agent or toxin. Note that for a single agent, the economic cost of associated disease may vary considerably between a country in which the biological agent is endemic, and a

country that is free of the biological agent. Where specific morbidity, mortality, and economic estimates are available, the source and context of the information must be provided. For example, existing risk analysis performed for import or export in association with a country or region may be used as a valuable source of economic data.

5. Perform the biological risk assessment, assigning a likelihood ranking and a severity ranking for agent release and for exposure to susceptible animals and humans for **each** laboratory procedure involving the biological agent or toxin in the laboratory (e.g. specimen receipt, necropsy, amplification in culture, centrifugation, nucleic acid extraction, storage, archive, animal experimentation, etc.) Biosafety assessments address the likelihood and severity of inadvertent exposure and of release of the biological agent. Biosecurity assessments address theft, loss, and intentional misuse of a biological agent.

6. Identify appropriate risk control measures available to the laboratory, including those biosafety and biosecurity measures already in place and those which could be implemented. There are often several different control measures that when used alone or in combination can provide equivalent results at similar or widely different costs. Each biosafety and laboratory biosecurity measure or combination of measures must be evaluated independently in order to determine the relative effectiveness in reducing the overall risk of exposure and release. It is the responsibility of the laboratory managers with the local, national, and regional disease control authorities to determine the economic and logistical feasibility of different control measures and appropriately balance the risks and benefits associated with the presence and handling of the biohazard.

7. Document the information and approach used in the risk assessment. The documentation must be complete, including data, methods of analysis, results, discussion, explanatory notes, and conclusions, dates and responsible personnel. References should be provided when relevant scientific and laboratory data and information is used (e.g. infectious dose, routes of transmission, working concentrations, environmental stability, etc.). All assumptions used must be identified and justifications for the assumptions must be provided.

8. Maintain or implement the selected biological risk control measures (biosafety and biosecurity practices) in the laboratory.

9. Make a record of and communicate the complete risk analysis, including implementation of the biosafety and biosecurity measures to the appropriate authorities and stakeholders. There are multiple report formats and templates available for documenting risk analysis. Examples can be found in the WOAH *Handbook on Import Risk Analysis for Animals and Animal Products* (WOAH, 2010a; 2010b) and in the *Seven Cardinal Rules of Risk Communication* (Covello & Allen, 1988).

APPENDIX 1.1.4.2.

CONSIDERATIONS USED IN EVALUATING AND IMPLEMENTING BIOLOGICAL RISK CONTROL MEASURES

Chapter 2.1.3 Managing biorisk: examples of aligning risk management strategies with assessed biorisks *provides illustrative examples of agent-specific risk assessments.*

Considerations used for identifying and assessing laboratory hazards	Determinant or level of risk for release from laboratory or exposure of staff	Examples of biological risk control measures
Epidemiology of the biological agent; routes of transmission, including aerosol, direct contact, fomites, vectors; infectious dose, susceptible species, and likely extent of transmission. Origin of the agent outside the host.	Route(s) of transmission determines possible mechanisms for exposures or release from a laboratory. Origin of samples: specimens derived from wildlife may contain human or animal pathogens not normally encountered. Geographical source of specimens.	Different routes of transmission require specific mitigation measures: - Aerosols: use of primary containment (e.g. biosafety cabinets), good microbiological technique (GMT), air filtration, directional airflow. -Surface contamination: disinfection, PPE including clothing and gloves, showering out of the laboratory. -Solid and liquid waste: waste treatment measures (e.g. autoclaving, chemical) -Fomites and materials exiting the laboratory: decontamination strategies
May cause human or animal disease; *Severity of harm for laboratory workers, public health, and animal health*.	Severe: potentially fatal disease, treatment or prophylaxis generally not available. Human: high individual or community risk. Animal: exotic or enzootic, subject to official control and that have high risk of spread from the laboratory into the environment and national/regional animal population.	Avoid release of the agent using a combination of administrative, operational, and engineering controls, and PPE. Considerations include stringent measures for biocontainment, decontamination and disinfection, redundancy of control measures used, GMT; mandatory training and competency for workers; mandatory employee health reporting programmes; mandatory laboratory security policies and procedures: redundancy of control measures, access control, due diligence in authorising personnel, inventory of seed and working stocks, intrusion detection, emergency response plans.
	Moderate: effective prophylaxis and treatments are generally available, but may be variable in effectiveness. Human: high individual risk, low community risk. Animal: exotic or enzootic, subject to official control and have moderate risk of spread from the laboratory.	Use a combination of administrative, operational, and engineering controls and PPE. Considerations include GMT such as effective infection control procedures, decontamination and disinfection, use of PPE and biosafety cabinets; employee health programmes (e.g. vaccination when relevant, health reporting); mandatory training and competency for workers; laboratory security policies and procedures. Access controls, escort for unauthorised individuals, inventory of seed stocks.

Considerations used for identifying and assessing laboratory hazards	Determinant or level of risk for release from laboratory or exposure of staff	Examples of biological risk control measures
	Low: effective prophylaxis and treatments are available. Human: moderate individual risk, low community risk. Animal: either exotic or enzootic, subject to official control and have low risk of spread from the laboratory. Human: no or low individual and population risk. Animal: enzootic, not subject to official control.	Considerations include routine use of GMT such as decontamination and disinfection, effective infection control procedures including use of dedicated laboratory clothing, biosafety cabinets; basic training and competency for workers. Waste management, including disinfection of laboratory wastes. Considerations include routine use of good microbiological practices (see Section B.3 of this chapter).
Impacts associated with animal population morbidity and mortality, and associated economic consequences (e.g. trade, food security, costs of disease control and movement controls, destocking or vaccination) dependent on whether the agent is exotic or endemic to the country or region.	Severe: Unacceptable costs nationally.	Avoid release of the biological agent using a combination of administrative, operational, and engineering controls, and PPE. Considerations include stringent biocontainment measures; specific features that are warranted by route(s) of exposure; PPE; GMT, decontamination and disinfection, primary containment systems; mandatory training and competency; mandatory laboratory security policies and procedures: redundancy of control measures, access control, due diligence in authorising personnel, inventory of seed and working stocks, intrusion detection, emergency response plans.
	Moderate: financial costs assessed on a case-by-case basis.	Use a combination of administrative, operational, and engineering controls, and PPE. Considerations include GMT such as decontamination and disinfection, effective infection control procedures including the use of PPE, and biosafety cabinets; air and effluent control; mandatory training and competency, laboratory security: access controls, escort for unauthorised individuals, inventory of seed stocks.
	Low: financial impact at manageable or existing levels.	Considerations include GMT such as decontamination and disinfection, effective infection control procedures including use of laboratory clothing and biosafety cabinets; basic training and competency.

Considerations used for identifying and assessing laboratory hazards	Determinant or level of risk for release from laboratory or exposure of staff	Examples of biological risk control measures
Nature of the laboratory procedures to be conducted in a facility (e.g. small- versus large-scale amplification, use and storage of the agent.	Moderate to severe • Procedures such as antigen or vaccine production that generate large amounts of organism. • Aerosols generated by laboratory procedures (homogenisation, sonication, centrifugation). • Sample history: agents on primary isolation/low passage number are often more virulent than laboratory-adapted strains.	GMT such as decontamination and disinfection, the use of effective infection control procedures including the use of proper primary containment systems to physically separate the process from the other work areas. Staff safety including agent/procedure-specific training and medical surveillance. The containment area(s) should be designed to contain spillage of the entire contents of the closed system. Inadvertent carriage from the area to be taken into consideration depending on the epidemiology of the disease and the impact on the animal disease situation in the country or region. Mandatory laboratory security policies and procedures: redundancy of control measures, access control, due diligence in authorising personnel, inventory of seed and working stocks, intrusion detection, emergency response plans
	Low: • Vector or intermediate host required in the life-cycle of the agent does not naturally occur or survive in the country or region	GMT such as decontamination and disinfection, effective infection control procedures including proper laboratory design, use of dedicated laboratory clothing, primary containment systems such as biosafety cabinets, and disinfection of laboratory wastes may be adequate. The risk of inadvertent carriage from the laboratory to be considered depending on the epidemiology of the disease and the impact on the animal disease situation in the country or region.
Use of animals in association with the biological agent or toxin.	A higher level of risk may arise when agents are inoculated into laboratory animals. The following factors should be considered in the risk assessment: i) Host species versus inoculated species; ii) Strain, treatment and concentration of the inoculum; iii) Route of inoculation; iv) Animal housing; v) Types of sampling during the experiment. Examples: • Production of biological reagents (e.g. antibody) in animals • Animal-based diagnosis, pathogenicity determinations • Research	Good animal handling and microbiological technique such as decontamination and disinfection, infection control procedures, protective clothing and proper equipment. Staff training and medical surveillance. The facility should be designed to minimise or prevent spread of the biological agent or toxin through contaminated air, laboratory materials, liquid or solid waste or animal carcasses. Pest control. The room is considered primary containment for large animals. For laboratory animals individual vented cages, isolators, or similar provide primary containment. Security considerations include prevention of intentional animal or agent release as a form of biothreat: parameter fences, identification, intrusion alarms, redundancy of control measures.

Note: The control measures provided are not meant to be comprehensive, but are examples of available control measures. Comprehensive information on applicable biosafety and biosecurity measures is available in internationally recognised technical manuals such as the WHO Biosafety Manual (WHO, 2004), the Biosafety in Microbiological and Medical Laboratories (CDC, 2009) and related guides.

CHAPTER 1.1.6.

VALIDATION OF DIAGNOSTIC ASSAYS FOR INFECTIOUS DISEASES OF TERRESTRIAL ANIMALS

INTRODUCTION

Adequate validation and verification of the performance characteristics of diagnostic tests for infectious diseases are critical to ensuring that assays are applied and interpreted in a scientifically robust and defensible manner (Colling & Gardner, 2021). Since it was first adopted in 1996, the World Organisation for Animal Health (WOAH: founded as the OIE) Assay Development and Validation Pathway (Figure 1) has acted as the internationally recognised standard for the validation of veterinary diagnostic tests for infectious diseases.

Validation is a process that determines the fitness of an assay[1], which has been properly developed, optimised and standardised, for an intended purpose. All diagnostic assays regardless of whether they are used in the laboratory or as point-of-care tests should be validated for the species and specimen in which they will be used. Validation includes estimates of the analytical and diagnostic performance characteristics of a test. In the context of this chapter, an assay that has completed the first three stages of the validation pathway (see Figure 1 below), including performance characterisation, can be designated as "validated for the original intended purpose(s)". To maintain a validated assay status, however, the assay's performance should be carefully monitored under conditions of routine use, often by tracking the behaviour of assay controls within each run and through on-going assessment during routine diagnostic use in the targeted population over time. Should it no longer produce results consistent with the original validation data, the assay may be rendered unfit for its intended purpose(s).

Assays applied to individuals or populations have many purposes, such as aiding in: documenting freedom from disease in a country or region, preventing spread of disease through trade, contributing to eradication of an infection from a region or country, confirming diagnosis of clinical cases, estimating infection prevalence to facilitate risk analysis, identifying infected animals toward implementation of control measures, and classifying animals for herd health or immune status post-vaccination. A single assay may be validated for one or more intended purposes by optimising its performance characteristics for each purpose, e.g. setting diagnostic sensitivity (DSe) high, with associated lower diagnostic specificity (DSp) for a screening assay, or conversely, setting DSp high with associated lower DSe for a confirmatory assay (see Section A.1 Definition of the intended purpose(s) of an assay*).*

This chapter focuses on the criteria that must be fulfilled during assay development and validation of all assay types and the metrics used to characterise test performance. The inclusion of assay development as part of the assay validation process may seem counterintuitive, but in reality, three of the required validation criteria (definition of intended purpose[s], optimisation, and standardisation) that must be assessed in order to achieve a validated assay, comprise steps in the assay development process. Accordingly the assay development process seamlessly leads into an assay validation pathway, both of which require fulfilment of validation criteria. The guiding principles described herein also apply to infectious diseases that are not WOAH listed. More detailed guidance is provided in a series of recommendations for validation of diagnostic tests (Section 2.2 Validation of diagnostic tests, *chapters 2.2.1 to 2.2.8) that are tailored for several fundamentally different types*

1 "Assay," "test method," and "test" are synonymous terms for purposes of this chapter, and therefore are used interchangeably.

of assay (e.g. detection of antibodies, antigen and nucleic acids) and provide more information on specific issues related to the validation of diagnostic assays (Halpin et al., *2021). For specific information for wildlife species, refer to Chapter 2.2.7* Validation of diagnostic tests for infectious diseases applicable to wildlife (*Jia* et al., *2020; Michel* et al., *2021*). *The information provided in chapter 2.2.7, which is specific to wildlife species, might also be useful for domestic animal test validation, for example, where the number or availability of samples is limited.*

An up-to-date compilation of the relevant validation standards (WOAH and non-WOAH) and guidance documents for all stages of diagnostic test validation and proficiency testing, including design, analysis, interpretation as well as clear reporting and case studies are provided in the WOAH Scientific and Technical Review *issue Diagnostic Test Validation Science (Vol. 40, April 2021). Published standards for peer-reviewed reporting of accuracy studies (STARD) are available for infectious diseases of human, terrestrial (paratuberculosis, Bayesian latent class model) (Bossuyt* et al., *2015; Gardner* et al., *2011; Kostoulas* et al., *2017) and aquatic animals (Gardner* et al., *2019; Kostoulas* et al., *2021). Verification (Kirkland & Newberry, 2021) and comparability studies (Reising* et al., *2021) are briefly described at the end of this chapter for assays that have completed at least stage 2 of the WOAH pathway. There is a pressing need to develop validation guidelines and standards for the rapidly increasing use of point-of-care tests (POCTs). Typically, POCTs are used in the field under varying environmental conditions, on a range of sample types collected in non-sterile settings, by operators with a diverse range of experience, training and proficiency. Field-testing conditions, including extreme variations in temperature and humidity, as well as other variables such as water and reagent quality, an inadequate cold chain, operator ability, and poor or non-existent quality assurance systems, can all contribute to lower test accuracies than those reported by POCT manufacturers or obtained in an accredited laboratory (see Figure 1 Stage 5). The consequences of a positive test result and the need for confirmatory testing and reporting by an accredited laboratory in particular when performing a test for an exotic disease need to be embedded in existing testing policies and guidelines. POCT-specific standards and recommendations, such as the point-of-care key evidence tool (POCKET) checklist for multi-dimensional evidence reporting; scorecards and guidelines for POCT evaluation; and guidelines on quality practices in non-instrumented POCTs (i.e. those that do not require a specific piece of equipment) and ISO/TS 22583:2019 Guidance for supervisors and operators for POCT devices provide guidance for healthcare workers. In some countries, such as Germany, POCTs that detect notifiable and reportable animal diseases require formal authorisation by the national licensing authority. In other countries, POCT accreditation with organisations such as the WOAH and national testing authorities is encouraged but not mandatory (Halpin* et al., *2021; Hobbs* et al., *2020; and Section 2.5* Robustness and ruggedness *below*).

PRELIMINARY CONSIDERATIONS IN ASSAY DEVELOPMENT AND VALIDATION

All laboratories should comply with the requirements of Chapter 1.1.5 *Quality management in veterinary testing laboratories* (Newberry & Colling, 2021). This will minimise the influence of factors that do not depend on the test itself such as instrumentation, operator error, reagent choice (both chemical and biological) and calibration, reaction vessels and platforms, water quality, pH and ionicity of buffers and diluents, incubation temperatures and durations, and errors in the technical performance of the assay. Comprehensive and well-designed experiments are required to develop and optimise assays with favourable analytical characteristics. The underlying principles are broadly applicable to all assay types and, when conducted with appropriate rigour, provide the foundations for high-quality diagnostic tests that are fit for their intended purpose(s) Bowden *et al.* (2021). In their review of WOAH recommended diagnostic tests, Cullinane & Garvey (2021) concluded that enzyme-linked immunosorbent assay (ELISA) and molecular assays were the most commonly used WOAH-recommended tests, which is why examples in the following sections focus on these methods (Mayo *et al.,* 2021).

The first step in assay development is to define the purpose of the assay, because this guides all subsequent steps in the validation process. Assay validation criteria are the characterising traits of an assay that represent decisive factors, measures or standards upon which a judgment or decision may be based. By considering the variables that affect an assay's performance, the criteria that must be addressed in assay validation become clearer. The variables can be grouped into categories such as the: (a) sample – individual or pooled, matrix composition, and host/organism interactions affecting the target analyte quantitatively or qualitatively; (b) assay system – physical, chemical, biological and operator-related factors affecting the capacity of the assay to detect a specific analyte in

the sample; and (c) test result interpretation – the capacity of a test result, derived from the assay system, to predict accurately the status of the individual or population relative to the purpose for which the assay is applied.

Selection, collection, preparation, preservation and management of samples are critical variables in design and development of an assay to ensure valid test results. Other variables such as transport, chain of custody, tracking of samples, and the laboratory information management system are also key sources of variation/error that become especially important when the assay is used for routine testing. Integrity of laboratory-based experimental outcomes during assay development and validation is only as good as the quality of the samples used. Anticipating factors that can negatively impact sample quality must precede launching an assay validation effort. Reference samples used in assay development and validation should be in the same matrix that is to be used in the assay (e.g. serum, tissue, whole blood) and representative of the species to be tested by the assay. The reference materials should appropriately represent the range of analyte concentration to be detected by the assay. Virtual biobanks have become relevant resources with respect to reagents and samples during test development and validation. For example, once the genomic sequence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) became available, European Virus Archive Global (EVAg) Members rapidly developed virus stocks, diagnostic tests and positive controls and, within 10 weeks, over 1500 products had been distributed worldwide for diagnostic or research purposes (Watson *et al.,* 2021). Chapter 2.2.6 *Selection and use of reference samples and panels* provides an overview about selection and use of reference samples and panels to address relevant validation parameters such as repeatability, reproducibility, DSe and DSp etc. Information on sample collection, preparation, preservation, management, and transport is available in Chapters 1.1.2 *Collection, submission and storage of diagnostic specimens* and 1.1.3 *Transport of biological materials*.

The matrix in which the targeted analyte is found (serum, faeces, tissue, etc.) may contain endogenous or exogenous inhibitors that may interfere with the performance of the assay. This is of particular concern for enzyme-dependent tests such as polymerase chain reaction (PCR) or ELISA. Other factors that affect the concentration and composition of the target analyte (particularly antibody) in the sample may be mainly attributable to the host and are either inherent (e.g. age, sex, breed, nutritional status, pregnancy, immunological responsiveness) or acquired (e.g. passively acquired antibody, active immunity elicited by vaccination or infection). Non-host factors, such as contamination or deterioration of the sample, also potentially affect the ability of the assay to detect the specific targeted analyte in the sample. It is also important that biological reagents are free of extraneous agents that might otherwise lead to erroneous results.

THE CRITERIA OF ASSAY DEVELOPMENT AND VALIDATION

Accuracy and precision are two independent parameters which ultimately define the performance of a diagnostic test. Sensitivity, specificity and functions of these variables (e.g. likelihood ratios), change with the cut-off and represent accuracy while repeatability and reproducibility are measures of precision. A reliable test is accurate and precise. Assay performance is affected by many factors beginning with optimisation of the assay. After initial optimisation for an intended purpose, characteristics of the performance of the assay will be tested. The assay may need additional optimisation or may be found to be fit for purpose based on the results of the validation work. WOAH's Secretariat for Registration of Diagnostic Kits (SRDK) has a test validation and certification process where new tests, which are deemed to be fit for purpose(s) can be registered[2].

Criteria for Assay Development and Validation
i) Definition of the intended purpose(s)
ii) Optimisation
iii) Standardisation
iv) Repeatability
v) Analytical sensitivity
vi) Analytical specificity
vii) Thresholds (cut-offs)
viii) Diagnostic sensitivity
ix) Diagnostic specificity
x) Reproducibility
xi) Fitness for the intended purpose(s)

A. ASSAY DEVELOPMENT PATHWAY

1. Definition of the intended purpose(s) for an assay

Criteria for interpretation of results	
Positive predictive value	(PV^+)
Negative predictive value	(PV^-)
Positive likelihood ratio	(LR^+)
Negative likelihood ratio	(LR^-)

ISO/IEC 17025 (2017) for testing and calibration laboratories states that the laboratory shall use appropriate methods and procedures for all laboratory activities (Newberry & Colling, 2021). In other words, the assay must be 'fit for purpose'. Failure to define the purpose of testing *a priori* will likely lead to errors in both the design of the assay and in the determination of critical test parameters with the potential to invalidate the entire assay development and validation process and ultimately result in a test that does not meet the user's needs. Such errors may occur when, for example, an inappropriate reference population is selected that is heterologous to the population for which the test is being developed.

The qualitative and quantitative assessment of capacity of a positive or negative test result, e.g. predictive value and likelihood ratio to predict with high confidence the infection or exposure status of the animal or population of animals is the ultimate consideration of assay validation (Section B.4.2). This capacity is dependent on development of a carefully optimised and standardised (Section A.2.3) assay that, through accrual of validation data, provides confidence in the assay's ability to perform according to the intended purpose (Table 1).

In order to ensure that test results provide useful diagnostic inferences about animals or populations with regard to the intended purpose, the validation process encompasses initial development and assay performance documentation, as well as on-going assessment of quality control and quality assurance.

Figure 1 shows the assay validation process, from assay design through the development and validation pathways to implementation, deployment, and maintenance of the assay.

The first step of assay development is selection of an assay type that is appropriate and that likely can be validated for a particular use (fitness for purpose).

The most common purposes listed in the WOAH *Terrestrial Manual* are to:

1) Contribute to the demonstration of freedom from infection in a defined population (country/zone/compartment/herd) (prevalence apparently zero):
   - 1a) 'Free' with and/or without vaccination,
   - 1b) Re-establishment of freedom after outbreaks
2) Certify freedom from infection or presence of the agent in individual animals or products for trade/movement purposes.
3) Contribute to the eradication of disease or elimination of infection from defined populations.
4) Confirm diagnosis of suspect or clinical cases (includes confirmation of positive screening test).
5) Estimate prevalence of infection or exposure to facilitate risk analysis (surveys, herd health status, disease control measures).
6) Determine immune status of individual animals or populations (post-vaccination).

Table 1. Test purposes and relative importance of diagnostic sensitivity (DSe), diagnostic specificity (DSp), positive predictive value (PV^+), negative predictive value (PV^-), likelihood ratio of a positive test result (LR^+) and likelihood ratio of a negative test result (LR^-)

Purpose	Examples and measures of diagnostic accuracy depending on test purpose (Reid *et al.,* 2022)
1a) Historical freedom (with or without vaccination)	In a population that is historically free of a particular disease/pathogen, the prevalence is zero (or close to zero). To be fit for purpose, the test or test algorithm aims to minimise chances of false-positive results and ideally requires **high DSp**, **high PV^+ and high LR+.** This can be achieved by a single test with a high DSp or serial testing(*).
1b) Re-establishment of freedom after outbreak	During the course of a successful disease control programme, a gradual shift in prevalence from high (during the peak of the outbreak) to low (at the tail end of an outbreak) can be expected. During the early stages of a proof-of-freedom testing programme, when disease prevalence remains at non-negligible levels, a fit for purpose test needs a **high DSe**, **high PV^- and high LR^-.** This approach minimises the chances of false-negative results and allows detection of positive individuals. This can be achieved by a single test with a high DSe or parallel testing(*). At the end of the disease control programme when the remaining infected animals have been removed from the population, disease prevalence will be very low and so the proof-of-freedom testing algorithm will likely need to be altered to increase DSp (and thus improve PV^+ and LR^+) similar as in 1a.
2) Certify freedom from infection or agent in individual animals or products for trade/movement purposes	For the purpose of trade and movement the probability of false-negative results needs to be minimised. Otherwise, infected animals could be traded or moved with the potential to spread infection into non-infected, healthy populations. As the test is applied on individuals, no or little information is available about the prevalence or pre-test probability of infection. To be fit for purpose the test or test algorithm aims to minimise chances of false-negative results and ideally requires **high DSe**, **high PV^- and high LR^-**. This can be achieved by a single test with a high DSe or parallel testing(*).
3) Contribute to the eradication of disease or elimination of infection from defined populations	This purpose follows a similar pattern as in 1b, where prevalence is expected to decrease from high to low over time in a defined population.
4) Confirm diagnosis of suspect or clinical cases (includes confirmation of positive screening test)	The goal of a confirmatory test is to minimise the chances of a false-positive result. *Confirmation of clinical cases* For the purpose of confirmation of a clinical case ideally a test with a **high DSp, high PV^+** and **high LR^+** is needed. Because of the clinical manifestation of the disease and expected high pathogen load DSe is not considered to be as relevant. *Confirmation of positive screening samples* Screening tests are applied on healthy populations. They usually have a high DSe to ensure infected individuals are not missed. Only if confirmed by a confirmatory test with a high DSp the animal is considered positive. In this case the confirmatory test* needs to have a **high DSp**, **high PV^+** and **high LR^+**. This approach follows the series testing algorithm(*).
5) Estimate prevalence of infection or exposure to facilitate risk analysis	Epidemiologists require reliable estimates for test accuracy to design sampling plans for prevalence studies, surveys, herd health status and disease control measures. Using a screening test with a high DSe followed by a confirmatory test with a high DSp is a common approach for prevalence estimations.
6) Determine immune status a) in individual animals post-vaccination b) estimate sero-prevalence post-vaccination (research and monitoring of vaccine efficacy)	For this group the aim is to have a **high DSp, PV^+** and **LR^+**. A false-positive result could have fatal consequences because such an animal could in fact not be vaccinated/protected. The higher the accuracy of the test the more precise will be the estimate of post-vaccine seroconversion in individuals and populations. An example is the fluorescent antibody virus neutralisation (FAVN) test to assess the immune status of dogs and cats post-vaccination against rabies virus. For international travel a result of > 0.5 IU/ml is considered to represent acceptable protection.

(*)Multiple testing

Multiple testing consists of using more than one test to determine the infection status of an animal. The most common algorithms are testing in series or in parallel. For example, if two tests are used in series a sample is considered positive only if the first and the second test are positive. Series testing increases DSp but decreases DSe and increases PV^+ and LR^+. Confirmatory testing follows the series testing approach because a positive result from a screening test (high DSe) needs to be confirmed by a second test with a high DSp. The confirmatory test needs to have at least the same DSe as the screening test otherwise they could generate false-negative results, which would be considered a true-negative in this algorithm. Confirmatory testing increases DSp but decreases DSe, and increases PV^+ and LR^+. If two tests are used in parallel a sample is considered positive if any of the tests or both tests are positive. Parallel testing increases DSe but decreases DSp and increases PV^- and LR^-. In addition, for multiple testing algorithms to be effective screening and confirmatory tests should not be conditionally dependent (for example measure the same analyte, such as two ELISAs using the same antigen). Positive dependence in test sensitivity reduces the sensitivity of parallel test interpretation and a positive dependence in test specificity reduces the specificity of serial interpretation (Gardner *et al.,* 2000).

2. Assay development – the experimental studies

2.1. Test method design and proof of concept

Prior knowledge, thought and planning need to go into designing all steps of a new assay destined for validation, or an existing assay that is being modified. Assistance is offered in the recommendations for validation of diagnostic tests[3], which cover best practices for development and validation of assays for detection of various analytes e.g. antibody, antigen, and nucleic acid detection, Chapters 2.2.1 *Development and optimisation of antibody detection assays*, 2.2.2 *Development and optimisation of antigen detection assays*, and 2.2.3 D*evelopment and optimisation of nucleic acid detection assays*, respectively.

Development of any assay is dependent on analyte reference samples that reflect the target analyte, the matrix in which the analyte is found, and the population for which the assay is intended to be used. The reference samples may be sera, fluids (including meat juices) or tissues that contain the analyte of interest or a genomic construct consistent with the target analyte. These reference materials are used in experiments conducted throughout the development process and carried over into the validation of the assay.

Factors that affect the analytical characteristics of diagnostic assays are numerous and may vary according to each assay type, e.g. the main factors affecting the analytical characteristics of serological and molecular assays are described in Bowden *et al.* (2021).

For molecular assays, DSe is more dependent on the ability to obtain the target analyte in a processed sample from an animal that has the disease, than on the inherent ability of the assay to detect very low concentrations of analyte. Although an assay, such as real-time PCR, may be extremely sensitive analytically, this may not always translate to high DSe, due to the potential shortcomings of sampling (small volume, inhibitory substances, variations in the clinical spectrum of disease in an individual animal and efficiency of extraction). The inhibition of Taq polymerase due to sample characteristics may cause false-negative results in a test that otherwise has high analytical sensitivity (ASe). In addition, when evaluating two separate, real-time PCR assays for African swine fever virus (ASFV), it was found that both had comparable ASe (equivalent to 14 genomic copies of ASFV) when using a high-quality plasmid construct containing ASFV VP72 as a template. However, when evaluating various samples collected from clinically diseased pigs, the resulting DSe was determined to be 83% for one assay and 92% for the other (data not shown). The amplicon size of the assay with the lower DSe (250 base pairs or bp) was significantly larger than that of the other assay (75 bp). In general, amplification efficiency would be expected to decrease with increasing amplicon size. This characteristic becomes more pronounced when testing viral nucleic acids extracted from clinical samples, the quality of which may be affected by varying degrees of degradation. Such an outcome had not been evident when using plasmid as the template during determination of the assay's ASe. Furthermore, as an assay such as real-time PCR is so highly sensitive analytically, great care must be taken to prevent carry-over contamination with previously amplified template. Such contamination would cause a false-positive result in an assay that is otherwise also considered very highly specific (analytically) (Bowden & Wang 2021).

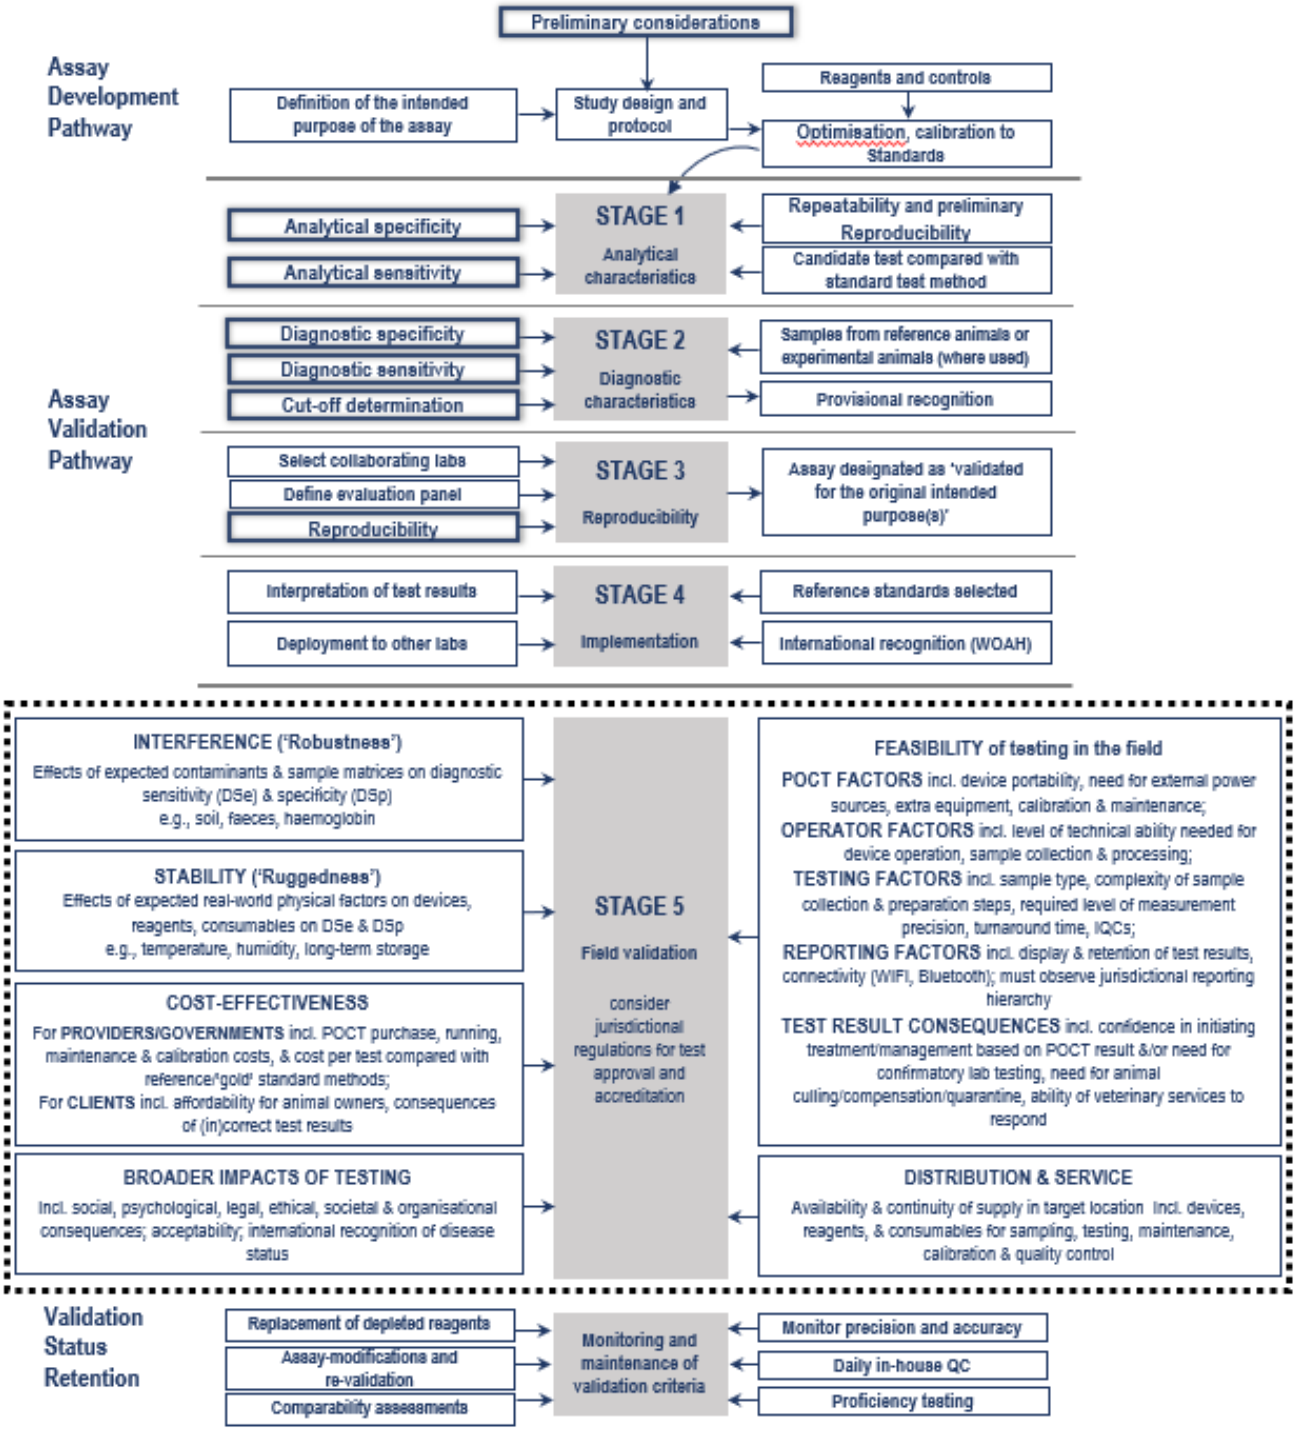

Fig. 1. Modified general assay development and validation pathways (Stages 1–4 and validation status retention) with validation criteria highlighted in bold typescript within shadowed boxes.
Specific criteria for the field validation of POCTs are added in Stage 5 within the dotted box (Halpin et al., 2021); (IQCs = internal quality control sample).

2.2. Standardisation and optimisation

Optimisation is the process by which the most important physical, chemical and biological parameters of an assay are evaluated and adjusted to ensure that the performance characteristics of the assay are best suited to the intended application. It is useful to select at least three well-defined reference samples, representing the analyte ranging from high positive to negative (e.g. strong positive, weak positive and negative). These samples ideally should represent known infected and uninfected animals from the population that will become the target of the assay. Obtaining such reference samples, however, is not

always possible, particularly for nucleic acid and antigen detection assays. The alternative of preparing reference samples spiked with cultured agents or positive sera is inferior as these samples do not truly represent the naturally occurring matrix-agent interaction (see also chapter 2.2.6). When no other alternative exists, spiking a sample with a known amount of the analyte or agent derived from culture, or diluting a high positive serum in negative serum of the same species may be all that is available. In either case, it is imperative that the matrix, into which the analyte is placed or diluted, is identical to, or resembles as closely as possible the samples that ultimately will be tested in the assay. Ideally, reference samples have been well characterised by one or preferably at least two alternate methodologies. These samples can be used in experiments to determine if the assay is able to distinguish between varying quantities of analyte, distinguish the target from closely related analytes, and for optimising the reagent concentrations and perfecting the protocol. In principle, for all assay types, it is highly desirable to prepare and store a sufficient amount of each reference sample in aliquots for use in every run of the candidate assay as it is evaluated through the entire development and validation process. Switching reference samples during the validation process introduces an intractable variable that can severely undermine interpretation of experimental data and, therefore, the integrity of the development and validation process.

The labour-intensive process of optimising an assay is fundamental and critical to achieving a reliable and predictable assay performance. Scientific judgment and use of best scientific practices, as provided in Bowden *et al.* (2021), are recommended to guide optimisation of all elements of assay development and validation. The approach outlined provides a solid foundation for development of a reliable assay. Often, prototype assays are developed using reagents and equipment at hand in the laboratory. However, if the assay is intended for routine diagnostic use in multiple laboratories, standardisation becomes critical. Every chemical and buffer formulation must be fully described. All reagents must be defined with respect to purity and grade (including water). Acceptable working ranges must be established and documented for parameters such as pH, molarity, etc. Standards for quality, purity, concentration and reactivity of biologicals must be defined. Shelf lives and storage conditions must also be considered for both chemicals and biologicals. Acceptable ranges for reaction times and temperatures also need to be established. Essential equipment critical to assay performance must be described in detail, including operational specifications and calibration. Process (quality) control should be an integral part of optimisation and considered from the very beginning rather than, as is often the case at the end of assay development. In addition to the above, downstream aspects such as data capture, data manipulation and interpretation may also require standardisation and optimisation. Finally, all of these parameters, once optimised, must be fully described in the test method protocol.

During optimisation of an assay, it is important to take note of procedural steps and assay parameters that have a narrow range in which the assay performs optimally, as these are the critical points that ultimately affect an assay's reliability (see Section A.2.7). For some assay types, specific steps in the procedure may have more impact than other steps on the final assay performance (see Section B.5 below and Chapter 2.2.8 *Comparability of assays after changes in a validated test method* for additional information on establishing comparability when reagents or processes are changed; also Reising *et al.,* 2021).

A variety of analyte reference samples and other process controls that are routinely included in any assay system are identified in the following sections. These provide critical assay monitoring functions that require special attention during assay optimisation. In addition, attention must be paid to the proper preparation and storage of all biological reagents and reference materials to ensure stability (see Chapter 1.1.2; Watson *et al.,* 2021).

2.3. Operating range of the assay

The operating range of an assay is the interval of analyte concentrations or titres over which the method provides suitable accuracy and precision. Accuracy is the closeness of a test value to the expected (true) value (mean or median) for a reference standard reagent of known concentration or titre. Precision is the degree of dispersion (variance, standard deviation [SD] or coefficient of variation [Cv]) within a series of measurements of the same sample tested under specified conditions. Laboratory sources of variation that affect assay precision include: 1) within a single test run, 2) between concurrent runs, 3a) between assay runs at different times in the same day or on different days under similar conditions, 3b) between assay runs on different days with different operators, 4) between laboratories. In this chapter, categories 1–3 are estimates of repeatability, and category 4 is synonymous with reproducibility. The repeatability of results of operators in different laboratories is likely to be lower (higher SD, higher Cv) than that of operators working in the same laboratory. During development of the assay, the lower and upper limits of the operating range are determined. To formally determine this range, a high positive reference sample is

usually selected (ideally, this sample will be the same one from among the three samples described in Section A.2.3 below). This high positive sample is serially diluted to extinction of the assay's response in an analyte-negative matrix of the same constitution as the sample matrix from animals in the population targeted by the assay. The results are plotted as a 'response-curve', with the response (e.g. optical density, cycle threshold, counts of pathogens, etc.) a function of analyte concentration (amount). The curve establishes the working range of the assay. If the range is found to be unacceptable for the intended purpose, additional optimisation may be needed. The typical calibration curve for most assays is sigmoidal in shape. The data are transformed to approximate a linear relationship between response and concentration using a suitable algorithm (Findlay & Dillard, 2007).

2.4. Inhibitory factors in the sample matrix

Each different matrix to be used in an assay must be used in the validation process. Some sample matrices include inhibitory factors that interfere with the performance of specific types of assays. Serum, particularly if haemolysed, may contain factors toxic to the cells used in viral neutralisation assays, while endogenous substances found in some tissues and fluids can interfere with or inhibit ligand-binding and enzymatic-based assays such as ELISAs. Faeces, autolysed tissues and semen samples tend to contain more interfering substances and are therefore more problematic for assay performance than are serum, blood or fresh tissues. For molecular assays, inhibitors of enzymes in the reaction mix, interferents and degradants may be present in the matrix. Selectivity is essentially the test for detection in the presence of inhibitors. Sample matrix variation is one of the most important, but may be among the least acknowledged, sources of error in analytical measurements. Assessment of ASp should use matrices relevant to the intended purpose, such as solid tissue, whole blood and swabs. Interfering substances (inhibitors) can originate from the samples, e.g. haemoglobin (Schrader *et al.,* 2012; Wilson, 1997), from the environment, or from the process of sample collection and transport (e.g. media and anticoagulants) (Druce *et al.,* 2012; Garcia *et al.,* 2002; Gibb *et al.,* 1998; Miyachi *et al.,* 1998; Yokota *et al.,* 1999;). For example, whole blood is one of the most important and common samples submitted for Hendravirus (HeV) real-time RT-PCR testing. It was found that lithium heparin, a common anticoagulant, had a significant impact on HeV real-time RT-PCR testing, producing false-negative results. In contrast, the anticoagulant ethylenediamine tetra-acetic acid (EDTA) had a comparatively low inhibitory effect. Furthermore, for the real-time RT-PCR assay for detecting bluetongue virus (BTV), diluting blood 1/10 (volume per volume or v/v) in phosphate-buffered saline resulted in improved sensitivity, evidenced by lower Ct values, in comparison to undiluted blood. A recent review of the different types of internal controls available for monitoring the inhibition of real-time PCR-based assays (Yan *et al.,* 2020) provides information on internal control strategies as a routine quality management component in veterinary molecular testing. Data collected during the validation process concerning assay performance using the sample matrices being targeted will allow for a risk-based decision as to whether an inhibition control should be included for each sample or whether the test system is unlikely to be affected by inhibition. If inhibitory substances are a significant problem, an inhibition control must be included for each test sample (Section 1.2; Bowden *et al.,* 2021).

2.5. Robustness

Robustness refers to an assay's capacity to remain unaffected by minor variations in test situations that may occur over the course of testing. Assessment of robustness should begin during assay development and optimisation stages. The deliberate variations in method parameters may be addressed in experiments after optimal conditions for an assay are established. However, when multi-factorial titrations of reagents are used for optimising the assay, indications of a compromised robustness may surface. If slight differences in conditions or reagent concentrations cause unacceptable variability, the assay most likely will not be robust. Early knowledge of this situation elicits a critical decision point for determining whether to continue with validation of the assay would be worthwhile, because if an assay is not robust within one laboratory under rather ideal conditions, it is unlikely to be reproducible when transferred to other laboratories.

The factors most likely to affect assay robustness include pH, temperature, batch of reagents or brand of microtitre plates and aqueous or organic matrix factors (Bowden *et al.,* 2021; Dejaegher & Vander Heyden, 2006). Once optimisation is complete, the robustness of the assay becomes part of the assessment of repeatability. For point-of-care tests (POCTs) (see Figure 1 Stage 5), ruggedness (is expressed as the lack of influence on test results of operational and environmental variables of the analytical method) assessments are also necessary because POCT performance should not be easily affected by operator proficiency, fluctuations in temperature, humidity, sunlight, or other environmental factors.

2.6. Calibration of the assay to standard reagents

2.6.1. International and national reference standards

Ideally, WOAH or other international reference standards, containing a known concentration or titre of analyte, are the reagents to which all assays are standardised (see WOAH Guides[4] and also chapter 2.2.6). Such standards are prepared and distributed by WOAH Reference Laboratories or other international reference laboratories. National reference standards are calibrated by comparison with an international reference standard whenever possible; they are prepared and distributed by a national reference laboratory. In the absence of an international reference standard, a national reference standard becomes the standard of comparison for the candidate assay. These standards are highly characterised through extensive analysis, and preferably the methods for their characterisation, preparation, and storage have been published in peer-reviewed publications (Watson *et al.,* 2021).

2.6.2. In-house standard

An in-house reference standard generally should be calibrated against an international or national standard. In the absence of either of these calibrators and to the extent possible, the in-house standard is highly characterised in the same manner as international and national standards (see chapter 2.2.6). This local in-house standard therefore becomes the best available standard, and is retained in sufficient aliquoted volumes for periodic use as the standard to which working standards are calibrated.

2.6.3. Working standard

One or more working standards, commonly known as analyte or process controls, are calibrated to an international, national, or in-house standard, and are prepared in large quantities, aliquoted and stored for routine use in each diagnostic run of the assay.

2.7. 'Normalising' test results to a working standard

Due to the inherent variation in raw test results that are often observed between test runs of the same assay or among laboratories using the same or similar assays, it is almost impossible to compare directly (semi-) quantitative data. To improve markedly the comparability of test results both within and between laboratories, one or more working standard reagent(s) are included in each run of an assay. Raw test values for each test sample can then be converted to units of activity relative to the working standard(s) by a process called 'normalisation'. The 'normalised' values may be expressed in many ways, such as a per cent of a positive control (e.g. in an ELISA), or as the estimated concentration, e.g. genomic copies or titre of an analyte derived from a standard curve such as a cycle threshold (Ct) value in a hydrolysis probe assay. It is good practice to include working standards in all runs of the assay during assay development and validation because this allows 'normalisation' of data, which provides a valid means for direct comparison of results between runs of an assay. It is mandatory to control the (absolute) variation of the normalisation standards as otherwise normalisation can introduce a bias. For more information, see chapters 2.2.1, 2.2.2 and 2.2.3; Bowden *et al.* (2021).

2.8. Preliminary study of the repeatability

Assessment of repeatability should begin during assay development and optimisation stages. Early knowledge of this situation elicits a critical decision point for determining whether it is worthwhile to continue with validation of the assay.

Repeatability is further verified during Stage 1 of assay validation (Section B.1.1). When the optimised test is run under routine laboratory or field conditions (Stage 4 of assay validation), repeatability is continually monitored as part of process control procedures for the duration of the life of the assay (see Section B.5.1).

B. ASSAY VALIDATION PATHWAY

"Validation" is a process that determines the fitness of an assay that has been properly developed, optimised and standardised for an intended purpose(s). Validation includes estimates of the analytical and diagnostic performance characteristics of a test. In the context of this document, an assay that has completed the first three stages of the validation pathway (Figure 1), including performance characterisation, can be designated as "validated for the original intended purpose(s)". Lack of statistically robust numbers of samples from infected and non-infected animals is frequently observed with new and emerging zoonotic disease and can be a major obstacle to obtaining reliable accuracy estimates (Colling *et al.,* 2018; Stevenson *et al.,* 2021). In these circumstances tests with acceptable analytical sensitivity (ASe) and analytical specificity (ASp), repeatability and promising but preliminary DSe and DSp and reproducibility results based on a limited number of samples can be provisionally recognised by national authorities or trading partners until results from further testing confirm overall fitness for purpose. Well characterised samples have been used successfully for different purposes in interlaboratory comparison studies to assess fitness for purpose (Chapter 2.2.6; Gardner *et al.,* 2021). New platforms that can detect multiple pathogens simultaneously, e.g. multiplex technologies, high-throughput sequencing, biomarker assays and point-of-care tests represent new challenges for purpose-oriented validation studies (Bath *et al.,* 2020; Halpin *et al.,* 2021; Reid *et al*., 2021; van Borm *et al.,* 2016).

1. Stage 1 – Analytical performance characteristics

Ideally, the design of studies outlined in the following sections should be done with assistance of a statistician and a disease expert to ensure that the sample size and experimental approach are valid. It is possible to design experiments that efficiently provide information on likely within- and between-laboratory sources of variation in assay precision[5], which will define the performance characteristics of the assay. The choice of organisms, strains or serotypes to assess analytical sensitivity and specificity should reflect current knowledge and therefore inform the best possible experimental design for targeting specific analytes.

1.1. Repeatability

Repeatability is the level of agreement between results of replicates of a sample both within and between runs of the same test method in a given laboratory. Repeatability is estimated by evaluating variation in results of replicates. The number of replicates should preferably be determined in consultation with a statistician with a suggested minimum of three samples representing analyte activity within the operating range of the assay. Each of these samples is then aliquoted into the appropriate number of individual vessels as identical replicates of the original sample containing the original analyte and matrix concentration (see chapter 2.2.6). Each replicate is then run through all steps of the assay, including creating the working dilution, as though it were a test sample derived from the population targeted by the assay. It is not acceptable to prepare a final working dilution of a sample in a single tube from which diluted aliquots are pipetted into reaction vessels, or to create replicates from one extraction of nucleic acid rather than to extract each replicate before dilution into the reaction vessels. Such 'samples' do not constitute valid replicates for repeatability studies. Between-run variation is determined by using the same samples in multiple runs involving two or more operators, done on multiple days. Bowden & Wang (2021) provide an example for inter-assay repeatability of three ASFV real-time PCR assays that were evaluated using a weak-positive ASFV sample. The testing, including the extraction of viral DNA, was conducted on ten different days by different operators in the same laboratory. The variation in replicate results can be expressed as standard deviations, coefficients of variation (standard deviation ÷ mean of replicates), or other possible options (see chapter 2.2.4 *Measurement uncertainty* for assessments of repeatability).

1.2. Analytical specificity

ASp is the ability of the assay to distinguish the target analyte (e.g. antibody, organism or genomic sequence) from non-target analytes, including matrix components. The assessment is qualitative and the choice and sources of sample types, organisms and sequences for the ASp evaluation should reflect test purpose and assay type. See chapters 2.2.1, 2.2.2 and 2.2.3 for guidance for antibody, antigen and nucleic acid assays, respectively. For example, assessing the analytical specificity of a foot and mouth disease

5 Precision may be evaluated in several ways by testing the same replicated sample: 1) within a plate or plates in a run of the assay, 2) between plates run concurrently within a run of the assay, 3a) between assay runs at different times in the same day or on different days under similar conditions, 3b) between assay runs on different days with different operators, 4) between laboratories. In this chapter, precision categories 1–3 are estimates of repeatability, and precision category 4 is synonymous with reproducibility. Levels 3a and 3b are also known as intermediate precision.

(FMD) PCR could be performed by testing reference samples known to be positive for vesicular stomatitis virus, swine vesicular disease and/or malignant catarrhal fever. Analytical specificity assessments cannot determine the full range of potential cross-reacting analytes present in the population, or account for population-level sample variability; as such, determining the analytical specificity is not a surrogate for assessment of diagnostic specificity. ASp is documented during Stage 1 validation, and cross-reactions identified (Ludi *et al.,* 2021). Cross-reactivity (ASp less 100%) may be acceptable depending on the proposed use of the assay. The impact of cross-reactivity is further documented during Stage 2 (establishment of DSp) and assessed at Stage 4 implementation.

1.2.1. Selectivity

Selectivity refers to the extent to which a method can accurately quantify the targeted analyte in the presence of: 1) interferents such as matrix components (e.g. inhibitors of enzymes in the reaction mix; 2) degradants (e.g. toxic factors); 3) nonspecific binding of reactants to a solid phase (e.g. conjugate of an ELISA adsorbed to well of microtiter plate); and 4) antibodies to vaccination that may be confused with antibodies to active infection. Such interferents may cause falsely reduced or elevated responses in the assay that negatively affect its analytical specificity. Vessman *et al.* (2001) is a useful overview of selectivity as defined for analytical chemistry from which a modification described herein was deduced for application to diagnostic tests.

1.2.2. Exclusivity

Exclusivity is the capacity of the assay to detect an analyte or genomic sequence that is unique to a targeted organism, and excludes all other known organisms that are potentially cross-reactive. This would also define a confirmatory assay. For example, an assay to detect avian influenza virus (AIV) H5 subtypes should be assessed for cross-reaction with non-H5 AIV subtypes. Specificity testing should also include other organisms that cause similar clinical signs, to demonstrate the utility of the assay for differential detection of the target organism.

1.2.3. Inclusivity

Inclusivity is the capacity of an assay to detect several strains or serovars of a species, several species of a genus, or a similar grouping of closely related organisms or antibodies thereto. It characterises the scope of action for a screening assay, e.g. a group-specific bluetongue (BTV) ELISA that detects antibodies to all BTV serotypes or an NSP FMD ELISA that detects antibodies to all seven FMD serotypes .

1.3. Analytical sensitivity

The limit of detection (LOD) is a measure of the ASe of an assay. The LOD is the estimated amount of analyte in a specified matrix that would produce a positive result at least a specified percent of the time. Typically, estimated LOD will be based on spiking of the analyte into the target matrix. The choice of analyte(s) (e.g. species, strains) is part of the ASe definition and should be reported properly. These experiments may be designed for precise and accurate estimation of the probability point (e.g. 50% or 100%), but in some circumstances a conservative estimate of the LOD (e.g. 100%) may be acceptable. For example, in a titration using tenfold dilutions all replicates at all dilutions might show either 100% or 0% response. There are two choices at that point. The last dilution showing 100% response may be accepted as a conservative estimate of the lower limit of detection. A more accurate estimate may be obtained by a second stage experiment using narrower intervals in the dilution scheme focusing on the region between 100% and 0%. Methods for statistical evaluation of LOD data are in the Chapter 2.2.5 *Statistical approaches to validation*.

1.4. Analytical accuracy of ancillary tests or procedures

Some test methods or procedures may be qualified for use as analytical tools in the diagnostic laboratory. These usually are secondary tests or procedures that are applied to an analyte that has been detected in a primary assay. The purpose of such analytical tools is to further characterise the analyte detected in the primary assay. Examples of such adjunct tests include virus neutralisation to type an isolated virus, molecular sequencing and MALDI-TOF-MS (matrix assisted laser desorption ionisation time of flight mass spectrometry) for bacteria (Ricchi *et al.,* 2016).

Such ancillary tests must be validated for analytical performance characteristics (Sections A.2 through B.1.3, above). However, they differ from diagnostic tests because they do not require validation for diagnostic performance characteristics (Sections B.2 through B.4, below) if their results are not used to establish a final diagnosis with regard to the intended purpose. The analytical accuracy of these tools may be defined by comparison with a reference reagent standard, or by characteristics inherent in the tool itself (such as endpoint titration). Inthese examples, the targeted analyte is further characterised quantitatively or qualitatively by the analytical tool.

2. Stage 2 – Diagnostic performance of the assay

Diagnostic sensitivity
Percentage of known infected animals that test positive in the assay; infected animals that test negative are considered to have false-negative results.

Diagnostic specificity
Percentage of known uninfected animals that test negative in the assay; uninfected animals that test positive are considered to have false-positive results.

Animal samples used to assess DSe and DSp come from four main sources: (1) reference banks with samples of known infection status, (2) outbreak or surveillance samples where animal status is unknown but population status (infected or not infected) is known, (3) neither animal nor population status known, and (4) experimental challenge studies (see Table 3 for advantages and limitations of each method – in the Table, groups 2 and 3 are combined for brevity). DSe (proportion of samples from known infected animals that test positive in an assay) and DSp (the proportion of samples from known uninfected animals that test negative in an assay) are the primary performance indicators established during validation of an assay (see chapters 2.2.1., 2.2.2., 2.2.3). These estimates are the basis for calculation of other parameters from which inferences are made about test results (e.g. predictive values and likelihood ratios of positive and negative test results). Therefore, it is imperative that estimates of DSe and DSp are as accurate as possible. Ideally, they are derived from testing a panel of samples from animals of known history and infection status relative to the disease/infection in question and relevant to the country or region in which the test is to be used. An estimate of the area under the receiver operating characteristic (ROC) curve is a useful adjunct to DSe and DSp estimates for a quantitative diagnostic test because it assesses its global accuracy across all possible assay values (Greiner *et al.,* 2000; Zweig & Campbell, 1993). This approach is described in chapter 2.2.5.

Case definition, e.g. what constitutes an infected animal and what constitutes an uninfected animal, respectively, e.g. clinical signs, fever, results from a reference test, etc.

Reference samples: The designated number of known positive and known negative reference samples will depend on the likely values of DSe and DSp of the candidate assay and the desired confidence level for the estimates (Table 2 and Jacobson, 1998). Table 2 provides two panels of the theoretical number of samples required, when either a 5% or 2% error is allowed in the estimates of DSe or DSp. Many samples are required to achieve a high confidence (typically 95%) in the estimates of DSe and DSp when a small error margin in the estimate is desired. For example, comparison of a 2% vs 5% error for a likely DSe or DSp of 90% and 95% confidence shows a considerable increase (864 *vs* 138) in the number of samples required. For the most economically important listed diseases, 99% confidence might be preferred. Logistical and financial limitations may require that less than the statistically required sample size will be evaluated, in which case the confidence interval calculated for DSe and DSp will indicate less diagnostic confidence in the results. Sample size also may be limited by the fact that reference populations and WOAH reference standards may be lacking (see chapter 2.2.5 for further details). Therefore, it may be necessary to use fewer samples initially. It is, however, highly desirable to enhance confidence and reduce error margin in the DSe and DSp estimates by adding more samples (of equivalent status to the original panel) as they become available.

Table 2. Theoretical number of samples from animals of known infection status required for establishing diagnostic sensitivity (DSe) and specificity (DSp) estimates depending on likely value of DSe or DSp and desired error margin and confidence

Estimated DSe or DSp	2% error allowed in estimate of DSe and DSp			5% error allowed in estimate of DSe and DSp		
	Confidence			Confidence		
	90%	95%	99%	90%	95%	99%
90%	610	864	1493	98	138	239
92%	466	707	1221	75	113	195
94%	382	542	935	61	87	150
95%	372	456	788	60	73	126
96%	260	369	637	42	59	102
97%	197	279	483	32	45	77
98%	133	188	325	21	30	52
99%	67	95	164	11	15	26

The following are examples of reference populations and methodologies that may aid in estimating performance characteristics of the test being validated.

2.1. Reference animal populations

Ideally, selection of reference animals requires that important host variables in the target population are represented in animals chosen for being infected with or exposed to the target agent, or that have never been infected or exposed (Table 4). The variables to be noted include but are not limited to species, age, sex, breed, stage of infection, vaccination history, and relevant herd disease history (for further details see chapter 2.2.6). After the initial detection of a novel disease, reference samples may not exist or be in limited quantities. In these situations, samples from experimental challenge studies might be the only available sample for initial validation of assays.

2.1.1. Negative reference samples

True negative samples, from animals that have had no possible infection or exposure to the agent, may be difficult to locate. It is often possible to obtain these samples from countries or zones that have eradicated or have never had the disease in question. Such samples may be useful as long as the targeted population for the assay is sufficiently similar to the sample-source population.

2.1.2. Positive reference samples

It is generally problematic to find sufficient numbers of true-positive reference animals, as determined by isolation of the pathogen. It may be necessary to resort to samples from animals that have been identified by another test of sufficiently high accuracy, such as a validated nucleic acid detection assay. The candidate test is applied to these reference samples and results (positive and negative) are cross-classified in a 2 × 2 table. This has been called the “gold standard model” as it assumes the reference standard is perfect. A sample calculation is shown in Table 4 in Section B.2.5). Situations where a perfect reference is available for either positive or negative animals, and one where the reference is perfect for both are described for diagnostic test validation by Heuer & Stevenson (2021).

2.2. Samples from animals of unknown status

In some situations, the infection status of a population may be known. If the population is known to be non-infected, then all animals in that population are also assumed to be non-infected. In an infected population, not all animals will be infected especially if the disease is not highly contagious. Deducing the population’s status is more challenging if the infection is subclinical or covert or if animals are protected by vaccination

or prior exposure to a pathogen. When the so-called reference standard (true infection status) is imperfect, which is the rule with any diagnostic tests used to test field samples, estimates of DSe and DSp for the candidate assay based on this standard will be flawed. A way to overcome this problem is to perform a latent class analysis (LCA) of the joint results of two or more tests assuming neither test is perfect (e.g. Johnson *et al.,* 2019).

Latent-class models do not rely on the assumption of a perfect reference test but rather estimate the accuracy of the candidate test and a reference test using the joint test results (Branscum *et al.,* 2005; Enoe *et al.,* 2000; Georgiadis *et al.,* 2003; Hui & Walter, 1980). If a Bayesian framework is used for the LCA, prior knowledge about the DSe and DSp of the reference test and the candidate test can be incorporated into the analysis. The infection status of source populations can also be specified in a Bayesian LCA and inclusion of animal samples from known non-infected populations can enhance the ability of these models to estimate DSp and other parameters in the model (e.g. DSe and prevalence) more precisely than would occur if only data from two or more infected populations are used. Three key assumptions must normally be satisfied in a LCA: (1) when data from multiple populations are used, each population prevalence should be different; (2) the DSe and DSp of the test are constant across test populations; and (3) the tests are conditionally independent. However, if conditional dependence exists between the index and reference tests (e.g. they both measure a similar analyte), latent class models (LCM) with different dependence structure have been developed to model the conditional dependence among tests.

Because Bayesian latent class models are complex and require adherence to critical assumptions, statistical assistance should be sought to help guide the analysis and describe the sampling from the target population(s), the characteristics of other tests included in the analysis, the appropriate choice of model and the estimation methods should be based on peer-reviewed literature (see chapter 2.2.5 for details and Cheung *et al.,* 2021). Sample size calculations for a LCA require assistance from a statistician or epidemiologist with experience with the techniques.

Table 3. Source populations for test validation samples

Reference sample banks (e.g. from Ref. Labs)	Field populations with animals of unknown infection status	Experimental challenge trials
Advantages • Infection status known • Simple statistical analysis **Limitations** • Often not available for rare or new diseases • May not be representative of animals to be tested in the future • Clinical status, results of other tests and demographic information may be missing	**Advantages** • Representative of animals to be tested in future • Latent class models (LCM) used for data analysis: infection status of population and covariates can be added • Assessment of accuracy of multiple assays is possible **Limitations** • LCM requires expertise and training, and adherence to model assumptions	**Advantages** • Infection status based on challenge group • Assessment of "diagnostic window" of an assay **Limitations** • Samples from challenge trials may not mirror samples collected in the field • Often a secondary outcome in a pathogenesis study • Route of exposure, infectious dose, and other experimental conditions can be influential • Best suited to acute infections • Ethical considerations

2.3. Experimentally infected or vaccinated reference animals

Samples obtained sequentially from experimentally infected or vaccinated animals are useful for determining the kinetics of antibody responses or the presence/absence of antigen or organisms in samples from such animals (Table 3). However, multiple serially acquired pre- and post-exposure results from individual animals are not acceptable for establishing estimates of DSe and DSp because the statistical requirement of independent observations is violated. Single time-point sampling of individual experimental animals can be acceptable (e.g. one sample randomly chosen from each animal). Nevertheless, it should be noted that for indirect methods of analyte detection, exposure to organisms under experimental conditions, or vaccination, may elicit antibody responses that are not quantitatively and qualitatively typical of natural

infection in the target population (Jacobson, 1998). The strain of organism, dose, and route of administration to experimental animals are examples of variables that may introduce error when extrapolating DSe and DSp estimates to the target population. In cases when the near-impossibility of obtaining suitable reference samples from naturally exposed animals necessitates the use of samples from experimental animals for validation studies, the resulting DSe and DSp measures should be considered as "proof-of-concept" results and less than ideal estimates of the true DSp and DSe.

2.4. Selection of a cut-off (threshold) value for classification of test results

To obtain DSe and DSp estimates of the candidate assay, which is measured on a continuous scale, the test results must first be reduced to two (positive or negative) or three (positive, intermediate [doubtful] or negative) categories of test results. This is accomplished by insertion of one or two cut-off points (threshold or decision limits) on the scale of test results. The selection of the cut-off(s) should reflect the intended purpose of the assay and its application, and must support the required DSe and DSp of the assay. Options and descriptive methods for determining the best way to express DSe and DSp are available (Branscum *et al*., 2005; Georgiadis *et al.,* 2003; Greiner *et al.,* 1995; 2000; Jacobson, 1998; Zweig & Campbell, 1993; and chapter 2.2.5). If considerable overlap occurs in the distributions of test values from known infected and uninfected animals, it is impossible to select a single cut-off that will accurately classify these animals according to their infection status. Rather than a single cut-off, two cut-offs can be selected that define a high DSe (e.g. inclusion of 99% of the values from infected animals), and a high DSp (e.g. 99% of the values from uninfected animals) (Greiner *et al.,* 1995).

The main difficulty in establishing cut-offs based on diagnostic performance characteristics is the lack of availability of the required number of well-characterised (reference) samples. Alternatives are discussed in Section B.2.6 on provisional acceptance of an assay during accrual of data to enhance estimates of DSe and DSp.

2.5. Calculation of DSe and DSp based on test results of reference samples

A typical method for determining DSe and DSp estimates is to test the reference samples in the new assay, and cross tabulate the categorical test results in a 2 × 2 table. In a hypothetical example, assume the test developer has selected a sample size for DSe and DSp for the new assay under the assumption that the most likely values are 97% (DSe) and 99% (DSp), respectively, with a desired confidence of 95% for both estimates. The desired error margin in the estimates was set at 2%. Table 4 indicates that 279 samples from known infected animals are required for the DSe assessment, and 95 known negative samples are needed for establishing the DSp estimate. Assume that the samples were then run with the new assay. Table 4 is a hypothetical set of results from which DSe and DSp estimates have been obtained.

Table 4. Diagnostic sensitivity and specificity estimates calculated from hypothetical set of results for samples tested from known infected and non-infected populations

		Number of reference samples required*	
		Known positive (279)	Known negative (95)
Test results	Positive	270 TP	FP 7
	Negative	FN 9	TN 88
		Diagnostic sensitivity* TP/(TP + FN) **96.8%** (94.0 – 98.5%)**	Diagnostic specificity* TN/(TN + FP) **92.6%** (85.4 – 97.0%)**

*Based on Table 2 for an assay with the following parameters:
1) Prior to testing, estimated DSe of 97% and DSp of 99%
2) 95% = required confidence in DSe and DSp estimates
3) 2% = Error margin in the estimates of DSe and DSp
TP and FP = True Positive & False Positive, respectively
TN and FN = True Negative and False Negative, respectively
**95% exact binomial confidence limits for DSe and DSp calculated values
(see chapter 2.2.5 for information on confidence limits)

In this example, the DSe estimate is as anticipated, but the DSp is much lower (92%) than the anticipated value of 99%. As a consequence, the width of the confidence interval for DSp is greater than expected. Re-inspection of Table 2 indicates that 707 samples are necessary to achieve an error margin of ± 2% at a DSP of 92% but such an increase in sample size might not be feasible (see chapter 2.2.5 for further details).

2.6. Provisional assay recognition[6]

There are situations where it is not possible or desirable to fulfil Stage 2 of the Validation Pathway because appropriate samples from the target population are scarce and animals are difficult to access (such as for transboundary infectious diseases or wildlife diseases).

Experience has shown that the greatest obstacle for continuing through Stage 2 of the Validation Pathway is the number of defined samples required to calculate DSe and DSp. The formula is well known and tables are available for determining the number of samples required to estimate various levels of DSe and DSp, depending on the desired error margin and the level of confidence in the estimates (Table 2 and Jacobson, 1998). The formula assumes that the myriad of host/organism factors that may affect the test outcome are all accounted for. Since that assumption may be questionable, the estimated sample sizes are at best minimal. For a disease that is not endemic or widespread, it may be impossible, initially, to obtain the number of samples required, but over time, accrual of additional data will allow adjustment of the cut-off (threshold) or if no adjustment is needed, enhance confidence in the estimates.

Provisional recognition defines an assay that has been assessed through Stage 1 for critical assay benchmark parameters (ASe, ASp and repeatability) with, in addition, a preliminary estimate of DSp and DSe based on a small select panel of well-characterised samples containing the targeted analyte and a preliminary estimate of reproducibility. This represents partial completion of Stage 2. Preliminary reproducibility estimates of the candidate assay could be done using the select panel of well-characterised samples to enhance provisional acceptance status for the assay. The candidate test method is then duplicated in laboratories in at least two different institutes, and the panel of samples is evaluated using the candidate assay in each of these laboratories, using the same protocol, same reagents as specified in the protocol, and comparable equipment. This is a scaled-down version of the reproducibility study in Stage 3 of assay validation. In following this procedure of provisional recognition the test protocol must not be varied.

Provisional recognition
Test with acceptable ASe and ASp, repeatability and promising preliminary DSe and DSp based on a small select panel of well-characterised samples containing the targeted analyte and a preliminary estimate of reproducibility. Results can be provisionally recognised until adequate samples sizes for both DSe and DSp are obtained (refer to Table 2) and a more extensive reproducibility study is done to confirm overall fitness-for-purpose.

Provisional recognition of an assay by state or national authorities means that the assay has not been evaluated for diagnostic performance characteristics. As such, the laboratory should develop and follow a protocol for adding and evaluating samples, as they become available, to fulfil this requirement. Ideally, this process should be limited to a specific timeframe in which such an accrual would be directed toward fulfilling Stages 2 and 3 of the validation pathway, and to particular situations (emergencies, minor species, no other test available, etc.)

3. Stage 3 – Reproducibility and augmented repeatability estimates

3.1. Reproducibility

Reproducibility is the ability of a test method to provide consistent results, as determined by estimates of precision, when applied to aliquots of the same samples tested in different laboratories, preferably located in distinct or different regions or countries using the identical assay (protocol, reagents and controls). To assess the reproducibility of an assay, each of at least three laboratories should test the same panel of samples (blinded) containing a suggested minimum of 20 samples, with identical aliquots going to each laboratory (see chapter 2.2.6). This exercise also generates preliminary data on non-random effects attributable to deployment of the assay to other laboratories. In addition, within-laboratory repeatability estimates are augmented by the replicates used in the reproducibility studies. Measurements of precision

6 Provisional recognition does not imply acceptance by WOAH. It does, however, recognise an informed decision of authorities at local, state, national or international levels of their conditional approval of a partially validated assay.

can be estimated for both the reproducibility and repeatability data (see chapter 2.2.4 for further explanation of the topic and its application). Factors affecting testing reproducibility among laboratories and practical examples of proficiency testing and interlaboratory comparison testing are provided by Johnson & Cabuang (2021) and Waugh & Clark (2021). A case study with FMD for selection and use of reference panels is presented in Ludi *et al.* (2021) and the value of virtual biobanks for transparency purposes with respect to reagents and samples used during test development and validation is reported by Watson *et al.,* 2021.

For POCTs, reproducibility should be evaluated under the conditions of intended use.

3.2. Designation of a validated assay

On completion of Stage 3 validation, assuming the earlier stages have been fully and satisfactorily completed, the assay may be designated as "validated for the original intended purpose". Retention of this designation is dependent on continual monitoring of the assay performance, as described in Section 5.1.

4. Stage 4 – Programme implementation

The successful deployment of an assay provides additional and valuable evidence for its performance according to the expectations. Moreover, the (true) prevalence of the diagnostic trait in the target population is an important factor that needs to be accounted for as described below.

4.1. Fitness for use

While this chapter deals with validation and fitness for purpose from a scientific perspective, it should also be noted that other practical factors might impact the utility of an assay with respect to its intended application. These factors include not only the diagnostic suitability of the assay, but also its acceptability by scientific and regulatory communities, acceptability to the client, and feasibility given available laboratory resources. For some diseases, multiple assays might be available for use in combination in disease control and surveillance programmes and hence, an assay's utility might need to be assessed by evaluating incremental changes in DSe, DSp and predictive values of the combined tests.

An inability to meet operational requirements of an assay also may make it unfit for its intended use. Such requirements may include performance costs, equipment availability, level of technical sophistication and interpretation skills, kit/reagent availability, shelf life, transport requirements, safety, biosecurity, sample throughput, turn-around times for test results, aspects of quality control and quality assurance, and whether the assay can practically be deployed to other laboratories. Test kits used in the field are highly desirable from an ease-of-use viewpoint, but because they are performed outside the confines of a controlled laboratory environment, they require added precautions to maintain fitness for purpose (Crowther *et al.,* 2006; Halpin *et al.,* 2021). Examples supporting each of the six purposes are provided in Table 1 *Test purposes and relative importance of diagnostic sensitivity* (*DSe*), *diagnostic specificity* (*DSp*)*, positive predictive value* (*PV*$^+$), *negative predictive value* (*PV*$^-$)*, likelihood ratio of a positive test result* (*LR*$^+$) *and likelihood ratio of a negative test result* (*LR*$^-$).

4.2. Interpretation of test results

Predictive values of test results: The positive predictive value (PPV) is the probability that an animal that has tested positive is in fact positive with regard to the true diagnostic status. The negative predictive value (NPV) is the probability that an animal that has tested negative is in fact negative with regard to the true diagnostic status.

Predictive values of test results are an application of Bayes' theorem and are calculated as follows:

$$PPV = \frac{P\ x\ DSe}{P\ x\ DSe + (1-P)\ x\ (1-DSp)} \quad \text{and} \quad NPV = \frac{(1-P)\ x\ DSp}{P\ x\ (1-DSe) + (1-P)\ x\ DSp}$$

Where:

PPV = Predictive value of a positive test result

NPV = Predictive value of a negative test result

P = Prevalence of infection

DSe = Diagnostic sensitivity

DSp = Diagnostic specificity

In contrast to DSe and DSp, predictive values are influenced by the true prevalence of the true infection status of the target population. In other words, predictive values are not inherent characteristics of a specific diagnostic test, but are a function of its DSe and DSp and the local prevalence of infection in a defined population at a given point in time.

Predictive values are of great importance to field veterinarians for the interpretation of results. For example, a PPV of 0.9 means that an animal reacting positive to the test has 90% chance of being indeed infected and 10% probability of being a false positive.

The predictive value of a positive result also has great importance for the veterinary services in charge of the management of control or eradication programmes. If we consider the inverse of the PPV (i.e. 1/PPV) it gives the information on how much money is spent in the culling of true and false positives for each true positive animal detected by the surveillance activity. In other words, if the PPV is 0.67, it means that two positive animals out of three are true positives and the remaining is a false positive. Since during the application of a control programme, the prevalence of infection is continually changing, the monitoring of the PPV is a way of evaluating the costs of the programme.

Furthermore, during the application of a control programme it is usually advisable to change the sensitivity of the tests employed, based on the variation of prevalence of infection in the target population and on the objective of the programme, the PPV may be used to make the changes in DSe and DSp based on economic considerations. In other words, when the need for a change in DSe and DSp of the test arises, a number of putative cut-offs may be set along the ROC curve of the test validation and the relevant values of DSe and DSp for each cut-off may be used to evaluate the expected cost for the culling of each infected animal.

If the purpose is establishing evidence for freedom from disease, the NPV is the more important measure. The NPV critically depends on DSe. Whilst predictive values can be a useful tool in diagnostic test interpretation, they are highly dependent on the prevalence of disease in the population. Predictive values calculated in populations with high prevalence, or at the peak of an outbreak where disease prevalence is high, are not applicable in populations with low prevalence or at the tail end of an outbreak where disease prevalence is markedly decreased.

The likelihood ratio (LR) indicates the diagnostic power of a given test result and can be used to assist in test interpretation. The likelihood ratio is an inherent characteristic of the test; it depends solely on the combined diagnostic sensitivity and diagnostic specificity and therefore does not vary with prevalence. Likelihood ratios are extremely powerful, as they can be used to calculate the 'post-test' probability of disease, given the observed quantitative test result, and the diagnostician's assessment of the probability of infection, prior to the test being performed (Caraguel & Colling, 2021).

The LR is calculated as the ratio of the likelihood of a given test result occurring in infected individuals to the likelihood of the same test result occurring in non-infected individuals. If the LR is lower than one, the test result supports the absence of the infection, i.e. this test result is less likely to occur in infected animals than in non-infected animals. A LR equal to '1' means that the test result has no diagnostic power (i.e. it is as likely to occur in infected animals as it is in non-infected animals). The further the LR is away from one, towards either zero or infinity, the stronger the evidence provided by the test result. In the clinical context, test outputs with an LR > 10 or < 0.1 are considered good diagnostic evidence of the infection being either present or absent, respectively.

$$LR^{+} = \frac{DSe}{1 - DSp} \quad \text{and} \quad LR^{-} = \frac{1 - DSe}{DSp}$$

Where:

LR^{+} = Likelihood ratio of a positive test result

LR^{-} = Likelihood ratio of a negative test result

DSe = Diagnostic sensitivity

DSp= Diagnostic specificity

LR ranges from zero to infinity. If the LR of a given test result is greater than one, this test result supports the presence of the infection. LRs can be applied at the test cut-off or at different ranges of results.

4.3. International recognition

Traditionally, assays have been recognised internationally by WOAH when they are designated as prescribed or alternate tests for trade purposes. This has often been based on evidence of their usefulness on a national, regional or international basis. For commercial diagnostic kits that have gone through the WOAH procedure for validation and certification of diagnostic assays, the final step is listing of the test in the WOAH Register. Tests listed in the Register are certified as fit for a specific purpose if they have completed Validation Stages 1, 2 and 3 followed by supportive review from a panel of independent experts. The Register is intended to provide potential kit users with an informed and unbiased source of information about the kit and its performance characteristics for an intended purpose (Gifford *et al.,* 2021). The Register is available on the WOAH website (see footnote 2).

4.4. Deployment of the assay

Ultimate evidence of the usefulness of an assay is its successful application(s) in other laboratories and inclusion in national, regional and/or international control or surveillance programmes. Reference laboratories play a critical role in this process (Brown *et al.,* 2021). In the natural progression of diagnostic and/or technological improvements, recently validated assays may become the new standard method to which other assays will be compared. As such, they may progressively achieve national, regional and international recognition. As a recognised standard, these assays will also be used to develop reference reagents for quality control, proficiency and harmonisation purposes. These reference reagents may also become international standards.

An assessment of the reproducibility should be repeated when the test is transferred from the development laboratory to the field, whether for use in local laboratories or in field applications. Predictable changes, e.g. extremes of temperature and levels of operator experience, should be assessed as additional sources of variation in assay results that may affect estimates of reproducibility.

5. Monitoring assay performance after initial validation

5.1. Monitoring the assay

To retain the status of a validated assay it is necessary to assure that the assay as originally validated consistently maintains the performance characteristics as defined during validation of the assay. This can be determined in a quality assurance programme characterised by carefully monitoring the assay's daily performance, primarily through precision and accuracy estimates for internal controls, as well as outlier tendencies (1.1 Repeatability). The performance can be monitored graphically by plotting measurements from assay controls in control charts[7] (Crowther *et al.,* 2006). Deviations from the expected performance should be investigated so corrective action can be taken if necessary. Such monitoring provides critical evidence that the assay retains its "validated" designation during the implementation phase of the assay. Reproducibility is assessed through external quality control programmes such as proficiency testing (Johnson & Cabuang, 2021) (3.1 Reproducibility). Should the assay cease to produce results consistent with the original validation data, the assay would be rendered unfit for its intended purpose. Thus, a validated assay must be continuously assessed to assure it maintains its fitness for purpose (Waugh & Clark, 2021).

5.2. Modifications and enhancements – considerations for changes in the assay

Over time, modifications of the assay will likely be necessary to address changes in the intended purpose, analytes targeted (i.e. modification of the assay to adjust diagnostic performance) or technical modifications to improve assay efficiency or cost-effectiveness. For a change in intended purpose of the assay, then a revised validation from Stage 2 onwards is obligatory.

If the assay is to be applied in another geographical region and/or population, revalidation of the assay under the new conditions is recommended. Lineages or sub-lineages of an infectious agent, derived from animals in different geographic locations, are known to vary requiring revalidation of the assay for the specified target population. This is especially true for nucleic acid detection (NAD) systems as it is very common for point mutations to occur in many infectious agents (especially RNA viruses). Mutations, which may occur within the primer or probe sites can affect the efficiency of the assay and even invalidate the

7 *Control chart:* A graphical representation of data from the repetitive measurement of a control sample(s) tested in different runs of the assay over time.

established performance characteristics. It is also advisable to regularly confirm the target sequence at the selected genomic regions for national or regional isolates of the infectious agents. This is especially true for the primer and probe sites, to ensure that they remain stable and the DSe and DSp for the assay are not compromised. Similar issues can arise with immunologically based assays for antigen or antibody.

A similar situation may occur with emergence of new subtypes of existing pathogens. In these circumstances, existing assays may need to be modified.

5.2.1. Technical modifications and comparability assessments

Technical modifications to a validated assay such as changes in instrumentation, extraction protocols, and conversion of an assay to a semi-automated or fully automated system using robotics will typically not necessitate full revalidation of the assay. Rather, a methods comparison study is done to determine if the relatively minor modification to the assay affected the previously documented performance characteristics of the assay. Comparability can be established by running the modified procedure and original procedure side-by-side, with the same panel of samples in both, over several runs. The panel chosen for this comparison should represent the entire operating range of both assays. If the results from the modified procedure and originally validated method are determined to be comparable in an experiment based on a pre-specified criterion, the modified assay remains valid for its intended purpose. See chapter 2.2.8 for description of experiments that are appropriate for comparability testing, chapter 2.2.6 on reference sample panels, Bowden & Wang, 2021 and Reising *et al.* 2021.

5.2.2. Biological modifications and comparability assessments

There may be situations where changes to some of the biologicals used in the assay may be necessary and/or warranted. This may include changes to the test specimen itself (e.g. a change in tissue to be tested or perhaps testing of a different species altogether). It may include changes to reagents (e.g. the substitution of a recombinant antigen for a cell culture derived antigen or one antibody conjugate for another of similar immunological specificity in an ELISA). The difficulty in making any modification lies in determining whether the change requires a complete revalidation of the assay at both bench and field levels. At the very least, any modification requires that the appropriate Stage 1 'analytical requisites' be assessed. The more difficult decision relates to Stage 2 'diagnostic performance'. To assist here, the original (reference) assay should initially be compared to the modified (candidate) assay in a controlled trial using a defined panel of positive and negative diagnostic samples. See chapter 2.2.8 and Reising *et al*. (2021) for a description of comparability assessment. If the comparability assessment does not suggest a change in diagnostic performance, the modified assay may be phased into routine use. If, on the other hand, differences in DSp and DSe are observed, the modified assay would require additional Stage 2 or field validation before being adopted.

> A **comparability study** is required when a change has been made in a test protocol of a validated test to ensure that test performance is comparable.

5.2.3. Replacement of depleted reagents

When a reagent such as a control sample or working standard is nearing depletion, it is essential to prepare and repeatedly test a replacement before such a control is depleted. The prospective control sample should be included in multiple runs of the assay in parallel with the original control to establish their proportional relationship. It is important to change only one reagent at a time to avoid the compound problem of evaluating more than one variable.

5.3. Enhancing confidence in validation criteria

Because many host variables have an impact on the diagnostic performance of assays, it is highly desirable over time to increase the number of reference samples or samples suitable for latent class analysis. The sampling design, collection, transportation, and testing environment for the new samples should be the same as used for the original validation study. Increases in sample numbers improves the precision of the overall estimates of DSe and DSp, and may allow calculations of DSe estimates by factors such as age, stage of disease, and load of organisms. Practical experiences show that regular updates of validation dossiers with new data is difficult. Participation in proficiency testing rounds using relevant panels with the latest strains may help to assist in proving ongoing assay accuracy and precision.

5.3.1. Data management

Long-term storage of data, review of validation data and on-going verification is an important component for enhancing confidence that assays are still performing with acceptable diagnostic accuracy. To achieve that goal, Laboratory Information Management Systems (LIMS) are required that integrate validation and diagnostic data to provide regular updates of assay performance. At a minimum, data management systems should facilitate: (1) storage of validation data in central locations, (2) review and/or sharing of data when, for example, assays are deployed to external laboratories (Stage 4 of the WOAH Assay Validation Pathway (see Figure 1), (3) on-going accrual and integration of diagnostic results to update the diagnostic characteristics of an assay (Stage 3 (see Figure 1), and (4) storage of Internal Quality Control (IQC) and External Quality Control (EQC) data for use in reviewing assay sensitivity (Stage 1, (see Figure 1), especially when changes to reagents or equipment occur.

Access and utilisation of LIMS for the purposes of test validation and ongoing verification remains limited, as they require significant investment and Information Technology expertise to maintain.

6. Verification of existing validated assays

If a laboratory is considering the use of a validated commercial kit or a candidate assay based on published literature with validation data, some form of verification will be required to determine whether the assay complies with either the kit manufacturer's or the author's assertions, with respect to Stage 1 validation criteria, in the context of the intended application. This may require a limited verification of both ASp and ASe using available reference materials, whether they be external and/or locally acquired from the target population. Once the laboratory is confident that the assay is performing as described from an analytical perspective, then proceeding to a limited Stage 2 validation should be considered in the context of the intended application and target population before the assay is put into routine diagnostic use (Kirkland & Newberry, 2021).

A **verification study** is required when a validated test is used in a new laboratory to ensure that results from the original validation study can be verified and overall test performance is comparable.

7. New technologies

The use of high-throughput sequencing (HTS) and opportunities for its application to diagnosis are growing rapidly; the major purposes are unbiased sequencing for pathogen discovery and targeted sequencing for detection and further characterisation. If the assay is used for detecting previously unidentified microorganisms, such as during an outbreak investigation, then the primary purpose is diagnostic. If the assay is used to further characterise a previously identified pathogen or to follow the molecular epidemiology of the pathogen during an outbreak, then its general purpose can be described as an ancillary test. In the absence of a known target analyte, following a traditional validation pathway is not possible. Monitoring quality metrics such as depth of coverage, uniformity of coverage, GC bias, base-call quality scores, decline in signal intensity or read-length, mapping quality and the inclusion of internal controls are used to assess relative performance of various HTS assays (Halpin *et al.*, 2021; van Borm *et al.,* 2016).

Another complexity in diagnostic test validation is the development of multiplexed assays such as bead-based assays and multiplexed real-time RT-PCR/PCR where more than one target is identified. Test accuracy of each of those targets in different concentrations and distribution is important and challenging to validate.

8. Conclusions

Adequate validation and verification of the performance characteristics of diagnostic tests for infectious diseases is critical to ensuring that assays are applied and interpreted in a scientifically robust and defensible manner (Colling & Gardner, 2021). Since it was first adopted in 1996, the WOAH Assay Development and Validation Pathway (Figure 1) has acted as the internationally recognised standard for the validation of veterinary diagnostic tests for infectious diseases.

Whilst the WOAH standard outlines a comprehensive approach to test validation, experience has demonstrated that assay developers continue to face a number of critical challenges in complying with many stages of the pathway. In identifying these obstacles, opportunities for improvement in diagnostic test validation standards, approaches and extension activities have been identified and are summarised in Table 5 (Reid *et al.,* 2022).

Table 5. Summary of challenges and opportunities for diagnostic test validation

Challenges	Opportunities
• What is the purpose of the test?	• Clearly define the purpose(s) and relevant associated parameters, e.g. screening test requires high diagnostic sensitivity and confirmatory test requires high diagnostic specificity
• Define scope and limitations of test	• What can be expected from the test (scope) and what cannot be expected (limitations)?
• Case definition: what constitutes an infected animal and what constitutes a non-infected animal?	• For example: positive in reference test(s), characteristic lesions, experimental infection, sample taken from an individual from a historically negative population, etc. if infection status is not known Bayesian latent class model (BLCM) may be applicable
• Is reference test imperfectly accurate or likely inferior to the new test under evaluation	• Use BLCM for estimation of diagnostic sensitivity and specificity, likelihood ratios, and other relevant parameters, e.g. prevalence
• Species and specimens	• Define species and specimen for which test will be validated, e.g. domestic chicken, nasopharyngeal swabs
• Source and target population	• Is source population (where test was validated) similar to target populations (where test will be applied)?
• Design, analysis, interpretation and reporting of validation/verification studies (lack of original validation data)?	• *Terrestrial Manual* chapters 1.1.6, 2.2.1–2.2.8, WOAH certification and registration process, STARD, ParaTB, Aquatic, BLCM, ISO/IEC 17025:2017, validation templates from national and international organisations & workshops provided by WOAH Reference Laboratories and Collaborating Centres
• Lack of samples (new and emerging, rare diseases, subclinical, wildlife diseases etc.)	• Reference panels of well described samples, if available, and samples for Interlaboratory Comparison (Network collaboration, "Vetlab"), Provisional Recognition

The thoroughness with which assays should be validated might seem a daunting task for diagnostic laboratories and research teams. However, resources are available to help plan and guide validation and verification studies, including relevant chapters of the WOAH *Terrestrial Manual*, the recent special issue of the WOAH *Scientific and Technical Review* on Diagnostic Test Validation (Colling & Gardner, 2021**)** and guidance documents published by national and regional accreditation bodies. International leaders in the field of diagnostic test validation, including the WOAH and their associated Reference Laboratories and Collaborating Centres, as well as national regulatory bodies, have an important role to play in continuing to develop the standards and systems required to ensure that assay developers have the resources required, and incentives, to meet their responsibilities to perform and report well designed and transparent validation studies. End users of diagnostic tests must also be supported to take responsibility to understand and verify assay performance in their own laboratories, and clearly communicate the uncertainty associated with diagnostic test results to their stakeholders.

CHAPTER 1.1.7.

STANDARDS FOR HIGH THROUGHPUT SEQUENCING, BIOINFORMATICS AND COMPUTATIONAL GENOMICS

INTRODUCTION

High throughput sequencing, bioinformatics and computational genomics (HTS-BCG) in animal health and food safety investigations should be used in accordance with standards for laboratory testing, just as any other laboratory tool or procedure. As HTS-BCG is a relatively new procedure, the purpose of this chapter is to assist laboratories by defining standards that will allow inclusion of the capability into a laboratory's scope of operations in a way in which the users of the results can have confidence.

A. GENERAL CONSIDERATIONS

Sequence information is playing an increasingly important role in the diagnosis and management of microbial infections, including in the characterisation of infectious agents, their possible phenotypic characteristics and their epidemiology. Consequently it is incumbent on laboratories to adopt policies and practices for generating, analysing and managing genomic sequence data that are based on accurate information and rigorously interpreted.

Increasingly, for full identification and characterisation of a microorganism, there is an expectation that essential features of its genome should be described. For viruses, this may be the whole genome, while for bacteria and parasites, it may be only partial sequences. However as sequencing technology is developing so rapidly, within a short time whole genome sequences for these larger microorganisms may also be routinely generated after suitable bioinformatics procedures have been developed.

The standards described here apply to the generation of genomic sequence data during investigations of infections of single animals, animal populations and their environment. They apply to the generation, management and use of such data within the accepted practices of veterinary investigations and within a laboratory's quality assurance system.

B. THE CONDUCT OF VETERINARY INVESTIGATIONS INCORPORATING HTS-BCG

Sequence data of microorganisms, such as is generated by HTS or metagenomics approaches, is only a tool, although a powerful one, to assist in the investigation of issues regarding animal health and food safety. Appropriate experts should perform the analysis of sequence data. The interpretation of that data in relation to the disease investigation should be led by suitably qualified veterinarians, consistent with the standard requirements for diagnosis of animal disease.

The sequence and sequence analysis of infections associated with cases, outbreaks and investigations of animal disease and food safety by laboratories should be recorded and analysed together with all other information relating to the reporting and recording of such cases and outbreaks. These data should be considered a necessary part of such reports and records.

HTS-BCG can be deployed for a range of purposes in the detection of infectious agents and their characterisation, either in biological material such as diagnostic or surveillance specimens or propagated in cultures or as isolates. For primary diagnostic applications, the users of the technology should consider the purposes of their testing in relation to the normal purposes of testing as defined in Chapter 1.1.6 *Validation Of diagnostic assays for infectious diseases of terrestrial animals*. HTS-BCG may also be applied as a confirmatory assay for organisms detected in some other primary assay, or to provide additional characterisation of such organisms.

Further to these general purposes of testing, HTS-BCG offers specific opportunities for:

i) The detection, identification and characterisation of previously unidentified microorganisms;

ii) The improved diagnosis of known diseases;

iii) The improved diagnosis of emerging or re-emerging diseases with known or unknown aetiology;

iv) The development of single 'universal' diagnostic assays, able to identify any potential pathogen;

v) The simultaneous and quick detection of multiple agents in diseases with multifactorial aetiologies;

vi) The increased capability to study the evolutionary dynamics of pathogens at the farm, local, national and global levels;

vii) The deeper understanding of the epidemiology of infectious diseases and the phylogeography of infectious agents;

viii) The enhanced traceability of infectious diseases and modes of pathogen transmission including applications in forensic epidemiology;

ix) More extensive characterisation of 'populations' of known pathogens (e.g. relevant minority strains, escape mutants) that in turn facilitates the design of better vaccines, antivirals, etc.;

x) Better links between pathogen genotype and phenotypes enabled through full genome sequence of multiple strains (including reference strains) of a single agent.

C. STANDARDS FOR THE USE OF HTS-BCG

1. Selection of a technology platform or service

Laboratories may choose to establish a HTS-BCG capability in-house, contract commercial suppliers of services or submit specimens to designated Reference Centres.

Where the laboratory establishes its own capability there are a number of commercially available sequencing platforms for the purpose of generating sequence information from test samples. The choice of platform should be based on a consideration of the intended purpose or combination of purposes as outlined in Section B above.

Of primary concern is that the technology selected is fit for the intended purpose, that it is appropriate for the production of sequence information from the types of genome intended for study. Other considerations may take into account the time required to conduct a sequencing run, including sample preparation; ancillary equipment needed in addition to the actual sequencing device; the capital cost of the purchase and set up of all necessary equipment and the cost of annual licences or service agreements, including manufacturer's recommended maintenance schedule; the availability of supporting expertise from the supplier; the cost of reagents for a sequencing run and the likely availability of reagents in the country concerned; the staff requirements and training required to operate the equipment and to conduct the associated bioinformatic analyses and the data management requirements. Currently available systems have been reviewed (Belák *et al.,* 2013; Granberg *et al*., 2016; Marston *et al*., 2013), but new models and technologies can be expected to become available frequently.

Where a laboratory or veterinary service contracts an external provider to supply HTS-BCG services, they should ensure that the service provider meets the standards defined in this chapter.

2. Sampling and reporting

HTS-BCG is a new technological tool in the management of diseases of animals and its use should be adopted within the context of tried and accepted processes for the management of animal health and food safety including clinical or epidemiological field investigations and the sampling of animals, animal populations or other epidemiologically relevant situations. The use of the technology should be appropriate to the purpose of the investigation, and the sampling strategy and the specimens taken should be appropriate for that investigation, based on an understanding of the pathogenesis and epidemiology of the infection under study or the likely pathogenesis and epidemiology of any novel infectious agent suspected. Such investigations should be under the supervision of appropriately qualified veterinarians.

In laboratories where HTS-BCG is used it should be managed within the context of the laboratory's quality assurance system. Hence the results of HTS-BCG must be interpreted in the context of the pathogenesis and epidemiology of the infection in the animal species under study. Results should be reported by appropriately qualified veterinary investigators with the authority to make diagnoses of animal diseases under the laboratory's quality assurance system and in the jurisdiction where the investigation is conducted.

3. Specimens and sample preparation

Specimens should be collected and submitted to the testing laboratory in accordance with the standards communicated in Chapter 1.1.2 *Collection, submission and storage of diagnostic specimens.* The normal comprehensive information regarding the individual animal, the case or reason for sampling and the relevant epidemiological information should be recorded in the laboratory's accessions processes, as for any submission to the laboratory.

As with other laboratory processes ensuring the integrity of the specimen and the samples to be tested is critical. Nucleic acids, either DNA or RNA, need to be extracted from the samples. In some cases, enrichment strategies to increase the ratio of pathogen to host nucleic acids can be used to maximise the sensitivity of the technique, however care must be taken to avoid biasing the outcome in the context of the intended purpose. Precautions to ensure the integrity and quality of nucleic acids must be followed similarly to any other molecular technique (e.g. polymerase chain reaction [PCR]) as already described in Chapter 2.1.2 *Biotechnology advances in the diagnosis of infectious diseases*. Once nucleic acids are extracted from the samples, they need to be further manipulated (e.g. reverse transcription of RNA into complementary DNA) in order to be used in HTS. Different technological platforms require specific sets of reagents in order to generate the final material ("libraries") ready for sequencing. Commercial kits are available for this purpose.

HTS is an extremely sensitive technology and even few molecules of nucleic acid could be detected. Hence, precautions to avoid cross-contaminations must be followed as in the case of many other molecular techniques used to detect nucleic acids (e.g. PCR). Separation of work areas from the possibility of cross contamination with nucleic acid from other molecular investigations is an essential requirement. In addition, HTS very frequently involves "multiplexing" of several samples in a single reaction. Individual samples are "tagged" during one of the stages of sample preparation by the use of short index sequences linked to nucleic acid molecules. Index sequences must be of sufficient quality and design to be relied on as a signature for the tagged library for HTS use in order to avoid artefacts during bioinformatics analysis of sequencing data obtained.

Every application of HTS-BCG technology should include positive and negative controls appropriate to the investigation and that have been incorporated through the sample preparation processes of the sequencing run as well as the actual run on the technology platform. Appropriate controls should be used to verify each step of the procedure including nucleic acid quality, library preparation, cross-contamination (including multiplexing) sensitivity and reproducibility.

As with any other diagnostic method, confirmation of results would require resampling of the original specimen, which therefore has to be protected from cross-contamination and be stored appropriately.

4. Generation of sequence data

While HTS platforms differ widely in their details, basic principles of quality control relevant to the technology can be followed, and generic recommendations for acceptable quality metrics can be made. Suitable control measures might include the use of positive, negative and no-template controls run in replicates of the test and a quality

scoring system. Sequencing quality metrics provide suitable parameters for the validation and monitoring of platform performance. Most platforms offer the possibility to spike controls in reagents and to use the control's QC metrics to monitor platform and reagent performance. Additional technology specific performance metrics can be used to monitor platform performance and to identify aberrant sequencing runs.

Quality metrics for the evaluation of the analytical performance of HTS-based tests, include:

i) Depth of coverage. This indicates the number of sequence reads providing information about a given nucleotide. When ongoing quality monitoring shows that the coverage depth at a given nucleotide is below the validated minimum coverage, confirmation should be provided using alternate methods (e.g. Sanger sequencing) or additional sequencing.

ii) Uniformity of coverage. This parameter describes how the depth of coverage is distributed over the test's target region(s). Deviations of uniformity of coverage from the validated range potentially indicate errors in the testing process.

iii) GC bias. The GC content (relative abundance of G and C nucleotides) of a target region affects the efficiency of sequencing reactions and will affect the uniformity of coverage. Where possible, the amount of GC bias in the test's target region(s) should be determined during validation and monitored to evaluate test performance.

iv) Base call quality scores. These are platform-derived reflections of the signal-to noise ratio and reflect the probability that the base call was correct. An acceptable raw base call quality threshold should be established during validation, and incorporated in bioinformatics filters to eliminate poor quality data during analysis.

v) Decline in signal intensity or read length. Depending on the exact application, HTS platform and chemistry, sequence reads have a typical distribution of read length and signal intensity. The expected signal intensity across reads (or read length distribution) should be established during validation and monitored for each run. Deviations in the distribution of read lengths may indicate problematic datasets.

vi) Mapping quality. This is a measure of uncertainty that a read is mapped properly to a genomic position within the target region. Acceptable values (e.g. proportion of reads mapping to the target) should be established during validation of bioinformatics workflows and the proportion of reads not mapping to the target can be monitored during each run.

vii) Internal controls. Most platforms offer the possibility to spike an internal control at very low frequency during the sequencing run. The quality metrics of those reads can to be compared to previously reported quality metrics.

5. Bioinformatics

An absolute requirement for any laboratory intending to establish a HTS-BCG capability is the employment of specialised bioinformatics skills. Even if platforms with supporting software for specific analyses in defined clinical situations were to become available the use of such packages would not remove the responsibility of the laboratory to be able to competently analyse its own data.

The bioinformatic analysis assembling the pathogen genomic sequence from the raw data and the subsequent secondary analysis are the critical elements in HTS-BCG. Hence the approaches used must be transparent and a declaration of the software packages, software versions, and reference databases or sequences used should be a component of every report of sequence analysis. Software programs used for these analyses must be readily available (commercially or open access) in order to be evaluated by the international community.

As with any laboratory procedure, attention must be given to quality assurance. The test method should include criteria for acceptance or rejection of each run based on the satisfactory analyses of the controls. Sequencing data must be documented to have satisfied minimum quality scores and coverage for each nucleotide of the assembled final consensus sequence obtained.

The appropriateness of chosen bioinformatics software for particular analyses can be evaluated through testing its performance against standard data sets containing data relating to agents expected to be present in the specimens to be tested.

6. Data management

The data generated from HTS-BCG operations are essential to reach the diagnosis or other scientific purpose of the investigation, such as agent characterisation, and are an integral component of the process. As such it is an essential requirement of laboratories to have policies, processes and supporting systems to curate, manage and store the data generated.

Different HTS technology platforms produce raw data in different formats and stage of pre-analysis, so it is necessary for laboratories to have policies and processes specific to the technology platform in use. Data management systems will include aspects of which data to keep, and the length of time for which they will be kept, and the back-up strategies to protect against accidental loss or deliberate erasure. Metadata describing the generation and analysis of the sequence data is essential, so that the process itself can be analysed or repeated.

Where a sequence analysis leads to an output of animal health significance, especially one of trade or international significance, it is an absolute requirement that the data on which the analysis was performed be kept available for audit or confirmatory analysis for a period of time commensurate with the significance of the animal health finding. This is particularly important where the finding may be disputed. Failure to be able to produce the required data for independent analysis could be taken to invalidate the finding.

Sequence data should be stored in a manner in which there is a clear link to the metadata associated with the specimen that was the subject of the analysis. As is standard practice in laboratory investigations, such metadata includes information regarding the animal sampled, its ownership and location, and accompanying clinical and epidemiological information regarding the animal population.

7. Validation of test systems for designated purposes

The concepts of test validation as stated in chapter 1.1.6 are broadly applicable to HTS-BCG. All procedures including sample processing (nucleic acid extraction, library preparation, tagging, target enrichment), sequencing, bioinformatics and reporting should be documented in SOPs before validation can start. Stage 1 validation data must be developed to confirm the analytic sensitivity (Se) and specificity (Sp) of the technique, and its repeatability. For sequencing based tests, analytic sensitivity can be defined as the likelihood that the assay will detect the targeted sequence variations, if present, at a given probability (e.g. 95% confidence), while analytical specificity can be defined as the probability that an assay will not detect a sequence variation when none are present at a given probability. Furthermore, each type of specimens has its own characteristics that have to be considered, e.g. nasal swab, sera or faeces. Well described samples with known concentrations of target analyte or non-target analytes and matrix components can be used to assess the analytical performance. This should include, as a minimum, serial dilutions of each type of specimen containing defined organisms to document the limits of detection of designated whole genomes or genetic sequences representative of the type for which the HTS-BCG capability will be used in the laboratory. For viral disease investigations, test specimens could be prepared to contain representative viruses of the full range of viral families from which agents may be present in test specimens of the type to be investigated in routine operations. Documentation of the laboratory's HTS-BCG system to detect these viruses will be established. The same principles apply to genetic markers, bacteria or other organisms for which the HTS-BCG capability will be used in planned routine operations. In all these runs designed to establish sensitivity and specificity, the sample preparation steps should be part of each assessment as these steps are likely to be critical to all aspects of overall test performance.

Several factors complicate the validation of NGS tests as primary diagnostic assays including:

i) The weight of the analytical and diagnostic validation required (chapter 1.1.6);

ii) The operational cost of the technology;

iii) The challenges of validation of a data analysis workflow;

iv) The high need for investment in hardware and expertise;

v) The time taken to obtain a result (currently days compared to hours for specific molecular diagnostics such as real-time PCR).

Confirmatory adjunct or secondary diagnostic assays need to be validated only for their analytical performance, e.g. analytical sensitivity and specificity, and repeatability and initial reproducibility (stage 1) and not to the full diagnostic extent (diagnostic sensitivity and specificity, stage 2).

It is recognised that it may not always be practical to produce large data sets on test performance such as would normally allow calculation of test diagnostic sensitivity and specificity, but other aspects of validation such as demonstration of test reproducibility among laboratories conducting similar investigations should be undertaken.

8. Quality assurance

Testing using HTS-BCG for the purposes of investigations of animal health and food safety should be conducted in accordance with the requirements of the laboratory's quality assurance system, the features of which will meet the standards listed in Chapter 1.1.5 *Quality management in veterinary testing laboratories.* Where the laboratory is accredited, the testing should be part of the laboratory's scope of accreditation.

Standard data sets against which the usefulness of bioinformatics software packages can be verified have been developed. Laboratories using HTS-BCG should ensure that their software packages for bioinformatics meet expected performance criteria against data standards.

Where proficiency testing strategies have been developed, laboratories using HTS-BCG should participate.

9. Interpretation of results

HTS-BCG can be used for a variety of purposes ranging from pathogen discovery to diagnosis or in-depth characterisation of known infectious agents. Consequently, the interpretation of the results obtained will be in the context of the specific clinical and epidemiological situation, reassured by satisfactory performance against all specified controls and quality assurance parameters. As with any other laboratory tests, these considerations are one among a number of parameters to be taken into account.

CHAPTER 1.1.8.

PRINCIPLES OF VETERINARY VACCINE PRODUCTION

SUMMARY

A reliable supply of pure, safe, potent, and effective vaccines is essential for maintenance of animal health and the successful operation of animal health programmes. Immunisation of animals with high quality vaccines is the primary means of control for many animal diseases. In other cases, vaccines are used in conjunction with national disease control or eradication programmes.

The requirements and procedures described here are intended to be general in nature and to be consistent with published standards that are generally available for guidance in the production of veterinary vaccines. The approach to ensuring the purity, safety, potency, and efficacy of veterinary vaccines may vary from country to country depending on local needs. However, proper standards and production controls are essential to ensure the availability of consistent, high quality products for use in animal health programmes.

As the pathogenesis and epidemiology of each disease varies, the role and efficacy of vaccination as a means of control also varies from one disease to another. Some vaccines may be highly efficacious, inducing an immunity that not only prevents clinical signs of the disease, but may also prevent infection and reduce multiplication and shedding of the disease-causing agent. Other vaccines may prevent clinical disease, but not prevent infection or the development of the carrier state. In other cases, immunisation may be completely ineffective or only able to reduce the severity of the disease. Thus the decision whether to recommend vaccination as part of an animal disease control strategy requires a thorough knowledge of the characteristics of the disease agent and its epidemiology, as well as the characteristics and capabilities of the various available vaccines. There is also growing public interest in the beneficial implications for animal welfare of the use of veterinary vaccines as a means of disease control. In any case, if vaccines are used, successful performance requires that they be produced in a manner that ensures a uniform and consistent product of high quality.

As for all medicines, vaccine production starts within research and development (R&D) facilities, carrying out all the preclinical studies which are intended to demonstrate the quality of the products, including the safety and the efficacy. All these studies are generally carried out according to international reference standards such as good laboratory practice (GLP) for preclinical studies and good clinical practice (GCP) for clinical studies.

Before release of a vaccine for use in a country, relevant regulatory approval must be requested from and be assessed and authorised by the competent authority to ensure compliance with local product regulatory requirements. Starting materials to be used, manufacturing steps, in-process controls and controls on the finished product before release by a responsible person should be described in the dossier for relevant regulatory approval, as should be the necessary tests to demonstrate quality, safety, and efficacy of the vaccine.

After the relevant regulatory approval has been granted by a competent authority, the industrial production can be launched in a manufacturing site which is authorised by the competent authority in accordance with national requirements and having the relevant equipment, facilities and personnel for production and controls. The manufacturing site should be inspected on a regular basis by experienced official inspectors.

Quality assurance is an integral part of the production of pure, safe and efficacious vaccines. This chapter outlines critical check points, with more details provided in Chapters 2.3.3 Minimum

requirements for the organisation and management of a vaccine manufacturing facility*, 2.3.4* Minimum requirements for the production and quality control of vaccines*, and 2.3.5* Minimum requirements for aseptic production in vaccine manufacture*. It is a step-wise and iterative process. Compliance with the full standards described in these chapters can be achieved through risk analysis and step-wise process improvement.*

NOMENCLATURE

The nomenclature for veterinary biological products varies from country to country. For example, in the United States of America (USA) the term 'vaccine' is used for products containing live[1] or inactivated viruses or protozoa, live bacteria, or nucleic acids. Products containing killed bacteria and other microorganisms are identified as bacterins, bacterial extracts, conventional or recombinant subunits, bacterintoxoids, or toxoids, depending on the type of antigen they contain. For example, products containing antigenic or immunising components of microorganisms may be called 'subunits' or 'bacterial extracts', and those produced from the inactivation of toxins are called 'toxoids'. In the European Union (EU), Immunological Veterinary Medicinal Products are defined as 'products administered to animals in order to produce active or passive immunity or to diagnose the state of immunity', see Directive 2001/82/EC, as amended by Directive 2004/28/EC. For this chapter, however, the term 'vaccine' will include all products designed to stimulate active immunisation of animals against disease, without regard to the type of microorganism or microbial toxin from which they may be derived or that they contain. This use is more consistent with international nomenclature. 'Vaccine' will not be used in this discussion in reference to biological products recommended for passive immunisation, immunomodulation, treatment of allergies, or diagnosis.

VACCINE TYPES OR FORMS

Vaccines may be prepared as live or inactivated (killed) products. Some live vaccines are prepared from low virulence, mild, field isolates of a disease-causing agent that have been found to be safe and effective when administered by an unnatural route or under other conditions where exposure to the microorganism will immunise rather than cause disease. Other live vaccines are prepared from isolates of disease-causing agents that have been modified by passage through laboratory animals, culture media, cell cultures, or avian embryos to select a variant of reduced virulence. The development of recombinant DNA (rDNA) procedures has provided some unique opportunities for vaccine production. Modified live vaccines may now be specifically produced by deletion of virulence-related genes from a microorganism. Others are produced by the insertion of genes that code for specific immunising antigens from a disease-causing microorganism into a nonvirulent vector microorganism. Nucleic-acid-mediated vaccines containing plasmid DNA have been developed. The DNA is usually in plasmid form and codes for immunising antigens from disease-causing microorganisms.

Killed products may contain: 1) Cultures of microorganisms that have been inactivated by chemical or physical means; 2) Inactivated toxins; or 3) Subunits (antigenic parts of microorganisms) that have been extracted from cultures or that have been produced through rDNA procedures.

Both live and inactivated vaccines may contain different antigenic components and may be formulated with adjuvants, stabilisers, antimicrobial preservatives and diluents. Adjuvants are designed to enhance the immunising efficacy of the vaccine. Those used frequently are typically water-in-oil emulsions (either single or double), made with mineral or vegetable oil and an emulsifying agent.

Other adjuvants, such as aluminium hydroxide gel or saponin, are also used. In addition to these traditional adjuvants, vaccines are being developed that include additional ingredients that induce immunomodulatory effects in the host animal and serve to enhance the efficacy of the product. These ingredients may include immunogenic components of microorganisms such as killed bacteria, which stimulate the immune response to other fractions contained in the vaccine, or cytokines, which may be used to regulate specific aspects of the immune system and are included in rDNA constructs used in products manufactured through biotechnology.

1 The generic term "live" (usually modified or attenuated) is used throughout this *Terrestrial Manual* to differentiate from inactivated organisms, although it is recognised that in the case of viruses they cannot be considered truly alive.

Many products obtained by biotechnology have now received relevant regulatory approval, and more are being developed. Products of rDNA technology do not differ fundamentally from conventional products. Therefore, existing laws and regulations are fully applicable to these new products.

Each competent authority with power to regulate organisms and products derived from recombinant techniques should ensure that the public health and the environment are protected from any potentially harmful effect. Veterinary vaccines derived through rDNA technology may be divided into three broad categories. The division is based on the products' biological properties and on the safety concerns they present.

Category I consists of non-viable or killed products that pose negligible risk to the environment and present no new or unusual safety concerns. Such products include inactivated microorganisms, either whole or as subunits, created by using rDNA techniques.

Category II products contain live microorganisms modified by adding or deleting one or more gene(s). Added genes may code for marker antigens, enzymes, or other biochemical by-products. Deleted genes may code for virulence, oncogenicity, marker antigens, enzymes, or other biochemical by-products. The relevant regulatory approval application must include a characterisation of the DNA segments added or deleted, as well as a phenotypic characterisation of the altered organism. The genetic modifications must not result in any increase in virulence, pathogenicity, or survivability of the altered organism in comparison with the wild-type form. It is important that the genetic modification does not cause deterioration in the safety characteristics of the organism.

Category III products make use of live vectors to carry recombinant-derived foreign genes that code for immunising antigens. Live vectors may carry one or more foreign gene(s) that have been shown to be effective for immunising target host animals. The use of DNA vaccines containing recombinant-derived foreign genes that code for immunising antigens (plasmid DNA vaccines) constitutes a new approach to vaccine development. The proper categorisation of this type of rDNA-derived product will be established as biological properties and safety characteristics are determined. These new vaccines may find application in a wide variety of situations much as conventional products have.

VACCINE PRODUCTION

1. Quality assurance

Quality assurance is a wide-ranging concept that covers all matters that individually or collectively influence the quality of a product. It is the total sum of the organised arrangements made with the object of ensuring that medicinal products are of the quality required for their intended use, ranging from process control, improvement and inspection, testing of the quality, efficacy and safety of the vaccines to assurance achieved through competent authority procedures. It is a step-wise and iterative process, and compliance with the standards described in these chapters can be achieved through risk analysis and step-wise process improvement. The basic concepts of quality assurance, good manufacturing practice (GMP), quality risk management and quality control are inter-related. See chapter 2.3.4 for full details.

2. Production facilities

Facilities used for the production of vaccines should be designed to protect the purity of the product throughout the production process, to safeguard the health of the personnel, and provide secure containment of any disease causing agents.

For each vaccine, there should be a detailed production plan that describes where each step in the production process will occur. This plan should be documented in a detailed standard operating procedure (SOP) or by providing a building blueprint and accompanying blueprint legend. Each room in the establishment should be uniquely identified, and all functions performed and all microorganisms involved should be specified for each room. Disinfection procedures, monitoring of equipment and other procedures used in the operation of the facilities to prevent contamination or errors during production should also be documented. This plan should be updated as new products or microorganisms are added to the facility, or other changes or improvements in procedures are developed.

The requirements for vaccine production facilities are described in more detail in chapter 2.3.3.

3. Documentation of the manufacturing process and record keeping

An Outline of Production (a highly detailed description of how the vaccine is produced and tested for release), a series of SOPs, or other documents should also be prepared to describe the procedure for the manufacture and testing of each product produced in an establishment.

Criteria and standards for acceptance for use of source materials should be clearly and accurately documented.

Guidelines for the preparation of such documents for veterinary vaccines are published by competent control authorities. This documentation is intended to define the product and to establish its specifications and standards. It should ensure, along with the blueprints and blueprint legends (or production plan and SOPs), a uniform and consistent method of producing the product and should be followed in the preparation of each batch/serial (one master batch record for each product).

The producer should establish a detailed record-keeping system capable of tracking the performance of successive steps in the preparation of each biological product. Records kept should indicate the date that each essential step was taken, the name of the person who carried out the task, the identity and quantity of ingredients added or removed at each step, critical measurements such as temperature and time, and any loss or gain in quantity in the course of the preparation. Records should be maintained of all tests conducted on each batch/serial. All records relevant to a batch/serial of product should be retained for at least 2 years after the expiry date on the label, or in line with the requirements of the competent control authority.

Details of documentation required at a manufacturing site are described in chapter 2.3.3.

4. Production

Because of the wide variety of products, the frequently large number of stages involved in the manufacture of vaccines and the nature of the biological processes, each stage must be constantly monitored. Adherence to validated operating procedures and in-process controls is critical.

The specifications and source of all product ingredients should be recorded in approved documents. The Outline of Production must be approved by the competent authority and is used for inspection and regulatory or legal action. Approval, by the regulatory authority, of documents that describe critical details of manufacture and testing is recommended. All ingredients of animal origin that are not subject to a validated sterilisation procedure should also be tested to ensure freedom from extraneous bacteria, fungi, mycoplasma, and viruses as specified in Chapter 1.1.9 *Tests for sterility and freedom from contamination of biological materials intended for veterinary use*. The country of origin should be known. Measures should be implemented by the manufacturer to avoid the risk of transmissible spongiform encephalopathy (TSE) agent contamination by ingredients of animal origin.

Some control authorities discourage the use of preservatives, especially antibiotics as a means of controlling adventitious contamination during production and prefer the use of strict aseptic techniques to ensure purity. However, they may allow the use of preservatives, particularly in multidose containers, to protect the product during use. These control authorities usually limit any addition of antibiotics in the manufacture of the product to cell culture fluids and other media, egg inocula, and material harvested from skin or possibly other tissues. Some control authorities prohibit the use of penicillin or streptomycin in vaccines administered by aerosol or parenterally. If the antibiotics used are not recommended for use in the target species, they should be shown to have no harmful effects in the vaccinated animals and not result in the contamination of food derived from vaccinated animals. Many countries ban thimerosal due to environmental concerns.

Details of vaccine production required at a manufacturing site, including requirements for starting materials, cell bank systems and seed-lot systems are described in chapter 2.3.3.

5. Process validation

Prior to obtaining relevant regulatory approval for any new product, each establishment should produce in its facilities three consecutive production batches/serials of completed product with satisfactory test results, to evaluate the consistency of production. The process used should follow the manufacturing procedure used to demonstrate efficacy and field safety as specified in the Outline of Production or equivalent documents. Some

authorities require that the size of each of the three batches/serials should be at least one-third the size of the average batch/serial that will be produced once the product is in production, so as to be typical.

The manufacturer should test each of these batches/serials for purity, safety, and potency as provided in approved documentation. Applicable standard requirements and test procedures, for example those described in United States Code of Federal Regulations [CFR] Title 9 Part 113, in the Annex to EU Directive 2001/82/EC (as amended), in the European Pharmacopoeia, or as described in this *Terrestrial Manual* may be used. Satisfactory test results should be demonstrated for all three batches/serials prior to approving the production of the product in the facilities and its release for marketing. Each subsequent batch/serial should be tested in the same manner with satisfactory results prior to release for marketing.

6. Stability tests

It is important to monitor the stability of each product through a programme to determine on-going stability.

Conditions of storage affecting the quality of the product should be taken into account as evaluated in the relevant regulatory approval, including light, temperature and the adhesive/absorptive properties of containers. All vaccines are sensitive to heat to some extent, but some are more sensitive than others. There is increasing interest in the development of vaccines that can tolerate adverse storage conditions. In this *Terrestrial Manual*, thermotolerant (see Glossary of Terms) is defined as the ability of vaccines to retain protective immunogenicity after exposure to temperatures above the storage temperature required according to the manufacturer's recommendations. Various electronic devices and heat-sensitive indicators are available to monitor cold chain temperatures. Specific thermotolerance claims should be supported by data from time–temperature studies undertaken under the relevant storage or transport conditions.

7. Tests to demonstrate safety and efficacy of a vaccine

All laboratory procedures and tests should be conducted in compliance with an international standard such as Good Laboratory Practice (GLP), see chapter 2.3.4. Similarly tests in animals should comply with Good Clinical Practice (GCP), including compliance with international standards for animal care and use. Submission of the results of the tests described below would normally be required in a dossier supporting a request for relevant regulatory approval.

7.1. Safety tests

7.1.1. Target animal safety tests

Harmonised international guidelines for safety tests are published by the International Cooperation on Harmonisation of Technical Requirements for Registration of Veterinary Medical Products (VICH) in VICH GL 44 Target animal safety for veterinary live and inactivated vaccines (http://www.vichsec.org/guidelines/biologicals/bio-safety/target-animal-safety.html). An overdose test is required for live vaccines shown to retain residual pathogenicity by induction of disease-specific signs or lesions. In general other vaccines do not require overdose testing.

For vaccines that require a single life-time dose or primary vaccination series only, the primary vaccination regimen should be used. For vaccines that require a single dose or primary vaccination series followed by booster vaccination, the primary vaccination regimen plus an additional dose should be used. The vaccination programme should be supported by the efficacy study design.

The intrinsic safety of vaccines should be demonstrated early in product development and documented as part of the regulatory approval dossier. Safety studies during development should include the safety of a single dose for all products, as well as the safety of an overdose and of repeated single doses for vaccines that require more than one dose during the lifetime of the animal. Additional data are derived for live vaccines from non-reversion to virulence studies and by assessing risk to the environment and in-contact animals, as discussed below. Safety should be demonstrated in each species and by each route for which the product is indicated. Safety in pregnant animals should be determined in separate, controlled studies using animals at appropriate stages of gestation.

For inactivated virus or bacterial products, where host animals are used for potency testing, some level of safety may be determined by measuring local and systemic responses following vaccination and before challenge in the potency tests. Further evidence concerning the safety of products is derived from field safety trials (discussed below). Vaccines derived through biotechnology should be evaluated as discussed in the classification of biotechnology-derived vaccines and release of live rDNA vaccines below.

7.1.2. Increase in virulence tests

With live vaccines, there is concern that the organism might be shed from the host and transmitted to contact animals, causing disease if it retains residual virulence or reverts to virulence with repeated host passages. Guidelines for testing are published by VICH: GL 41: Examination of live veterinary vaccines in target animals for absence of reversion to virulence (http://www.vichsec.org/guidelines/biologicals/bio-safety/target-animal-safety.html).

All live vaccines should be tested for non-reversion to virulence by means of passage studies. Vaccine organisms are propagated *in vivo* by inoculating a group of target animals of susceptible age, with master seed, not finished product; this inoculation uses the natural route of infection for the organism that is most likely to result in infection and reversion or a recommended route of administration of the vaccine manufactured from this master seed. The vaccine organism is recovered from tissues or excretions and is used directly to inoculate a further group of animals, and so on. After not less than four passages, i.e. use of a total of five groups of animals, the isolate must be fully characterised, using the same procedures used to characterise the master seed. Regulatory authority opinion varies in whether or not it is acceptable to propagate *in vitro* between passages organisms that otherwise cannot be passaged five times because of their degree of attenuation. The vaccine organism must retain an acceptable level of attenuation after propagation in this way.

7.1.3. Assessing risk to the environment

The ability of each live vaccine to shed, to spread to contact target and non-target animals, and to persist in the environment must be evaluated to provide information for assessing the risk of the vaccine to the environment, taking into account human health. In some cases this may be done in conjunction with the increase in virulence tests. In the case of live vaccines strains that may be zoonotic, the risk for humans should be assessed. These and additional considerations are especially important in the case of products based on biotechnology or recombinant DNA techniques; more information about such products is provided in other sections.

7.2. Efficacy tests

7.2.1. Laboratory efficacy

The efficacy of veterinary vaccines should be demonstrated by statistically valid vaccination–challenge studies in the host animal, using the most sensitive, usually the youngest, animals for which the product is to be recommended. Data should support the efficacy of the vaccine in each animal species by each vaccination regimen that is described in the product label recommendation. This includes studies regarding the onset of protection when claims for onset are made in the product labelling and for the duration of immunity. The tests should be performed under controlled conditions starting, wherever possible, with seronegative animals. Where validated potency tests are available, target species vaccination–challenge studies may not be required if predictive serological test results are available. The application of procedures to replace, reduce, and refine animal tests (the 'three Rs rule') should be encouraged whenever possible.

Efficacy studies should be conducted with final product vaccine that has been produced at the highest passage level from the master seed that is permitted in the Outline of Production, or equivalent approved documentation. This will have specified the minimum amount of antigen per dose that must be in the final product throughout the entire authorised shelf-life. Where a range of antigen level per dose is permitted, the antigen level per dose in the vaccine tested for efficacy must be at or below the minimum permitted amount. The precise challenge method and the

criteria for determining protection vary with the immunising agent, should have clinical significance, and should be standardised whenever possible.

Field efficacy studies may be used to confirm the results of laboratory studies or to demonstrate efficacy when vaccination–challenge studies are not feasible. However, it is generally more difficult to obtain statistically significant data to demonstrate efficacy under field conditions. Protocols for field studies are more complex, and care must be taken to establish proper controls to ensure the validity of the data. Even when properly designed, field efficacy studies may be inconclusive because of uncontrollable outside influences. Problems may include: a highly variable level of challenge; a low incidence of disease in non-vaccinated controls; and exposure to other organisms causing a similar disease. Therefore, efficacy data from both laboratory and field studies may be required to establish the efficacy of some products, as well as '*a posteriori*' field trials linked to vaccinovigilance.

7.2.2. Interference tests

Consideration must be given to possible interference between two different vaccines from the same manufacturer in the same container/ as a combined dose, or recommended to be given to the same animal within a 2-week period. The safety and the efficacy of this association should be investigated. Such studies are often termed "lack of interference studies" and should evaluate both interference of X on Y and X by Y. In some cases this can be determined serologically.

7.2.3. Field tests (safety and efficacy)

7.2.3.1. All vaccines

All veterinary vaccines administered to animals should be tested for field safety and, if feasible, for efficacy in the field, before being authorised for general use. Field studies are designed to demonstrate safety and efficacy under conditions of normal environment, care and use, and should detect unexpected reactions, including mortality that may not have been observed during the development of the product. Under field conditions there are many uncontrollable variables that make it difficult to obtain good efficacy data, but demonstration of safety is more reliable. The tests should be done on the host animal, at a variety of geographical locations, using appropriate numbers of susceptible animals. The test animals should represent all the ages and husbandry practices for which the product is indicated; unvaccinated controls must be included. The product tested should be two or more typical production batches/serials. A protocol should be developed indicating the observation methods and the recording methods.

7.2.3.2. Additional requirements for live rDNA products

The release of live rDNA microorganisms (Categories II and III) for field testing or general distribution as an approved product may have a significant effect on the quality of the human and animal environment. Before release is authorised, the manufacturers of the vaccine should conduct a risk assessment to evaluate the impact on the human and animal environment. In the USA, for example, a procedure is adopted that could be used as a model system in other countries. This is based on a "Summary Information Format" that summarises all sources and considerations of risk, including the results of laboratory testing, characterisation or sequencing of the master seed, and results of studies that address sources of risk to other species and the environment. The information included should allow the regulatory authority to conduct the risk assessment. If the results of the risk assessment are satisfactory, the regulatory authority will issue a formal document called a "Finding of No Significant Impact".

The EU has adopted a similar system. It is performed as follows:

A risk assessment is carried out that should contain the following information:

i) the purpose and need for the proposed action;

ii) the alternatives considered;

iii) a list of the government agencies, organisations, and persons consulted;

iv) the affected environment and the potential environmental consequences.

The topics discussed should include:

i) the characteristics of the vaccine organism;

ii) human health risks;

iii) animal health risks for both target and nontarget animals;

iv) persistence in the environment, and increase in virulence.

If the risk assessment results in a finding by competent authorities that the proposed release of the recombinant vaccine into the environment for field trials or general distribution would not have a significant impact on the environment, a notice should be published and distributed to the public announcing this and that the risk assessment and findings are available for public review and comment. If no substantive comments are received to refute the findings, competent authorities may authorise the field testing or grant the relevant regulatory approval for general distribution.

The preparation of a risk assessment and the findings made from the assessment may also include the scheduling of one or more public meetings if a proposed action has ecological or public health significance. Such meetings should be announced through a public notice. Interested persons should be invited to make presentations, along with presentations by the producer of the product, and government personnel. The transcripts of such meetings should become part of the public record.

If, in the course of preparing a risk assessment, competent authorities conclude that the proposed action may have a significant effect on the environment, an environmental impact statement (EIS) should be prepared. The EIS provides a full and fair discussion of the significant environmental impacts, and informs decision-makers and the public of any reasonable alternatives that would avoid or minimise the adverse impacts. Environmental documents are considered in the CFR Title 40 part 1508. The EU has issued guidelines under Directive 2001/18/EC: *Guideline on Live Recombinant Vector Vaccines for Veterinary Use,* see http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2009/10/WC500004590.pdf

8. Updating the Outline of Production

Before production procedures are changed, they should be approved by the regulatory authority. This is generally done by submitting an amended Outline of Production or equivalent documentation. Establishments should have internal review procedures to evaluate all changes in production before they are initiated.

In cases where a significant production step is altered, revisions may require additional data to support the purity, safety, potency, efficacy or stability of the product. In countries with regulatory systems that include confirmatory testing the final product at national laboratories, revisions may entail testing of the revised product before changes are approved by competent authorities.

QUALITY CONTROLS IN VACCINE PRODUCTION

1. Principle

Quality control is concerned with sampling, specifications and testing as well as the organisation, documentation and release procedures. Quality control ensures the necessary and relevant tests are carried out, and that materials and equipment are not released for use, nor products released for sale or supply, until their quality has been judged satisfactory. Quality control is not confined to laboratory operations, but must be involved in all decisions and specifications that may concern the quality of the product. The independence of quality control from production is considered fundamental to the satisfactory operation of quality control. Details of quality control are described in the chapter 2.3.4.

2. Batch/serial release for distribution

Prior to release, the manufacturer must test a representative sample of each batch/serial for purity, safety, and potency, as well as perform any other tests described in the firm's approved documentation of the manufacturing process for that product. In countries that have national regulatory programmes that include official control authority re-testing (check or confirmatory testing) of final products, samples of each batch/serial are submitted for testing in government laboratories by competent authorities prior to release for sale. If unsatisfactory results are obtained for tests conducted either by the manufacturer or by competent authorities, the batch/serial should not be released. In such cases, subsequent batches/serials of the product may be given priority for check testing by competent authorities.

2.1. Batch/serial purity test

Purity is determined by testing for a variety of contaminants, often defined by regulations. Tests to detect contaminants are performed on a representative sample of each batch/serial of final product prior to release.

Purity test procedures have been published, for example in CFR Title 9 part 113, in the annex to EU Directive 2001/82/EC (as amended), in the European Pharmacopoeia, or in this *Terrestrial Manual* (chapter 1.1.9), for the detection of extraneous viruses, bacteria, mycoplasma and fungi. Examples include tests for: *Salmonella*, *Brucella,* chlamydial agents, haemagglutinating viruses, avian lymphoid leucosis (virus), pathogens detected by a chicken inoculation test, or a chicken embryo inoculation test, lymphocytic choriomeningitis virus, cytopathic and haemadsorbing agents, and pathogens detected by enzyme-linked immunosorbent assay, polymerase chain reaction, or the fluorescent antibody technique.

2.2. Batch/serial safety test

VICH Guidelines 50 (inactivated vaccines) and 55 (live vaccines) provide for a waiver of the target animal batch/serial safety tests in recognition of the 3R principles. VICH Guideline 59 also provides for a waiver of the laboratory animal batch/serial safety tests (LABST) in recognition of the 3R principles. As stated in VICH Guidelines 50, 55 and 59 (http://www.vichsec.org/guidelines/biologicals/bio-safety/target-animal-safety.html), these batch safety tests may be waived by the regulatory authority when a sufficient number of production batches have been produced under the control of a seed lot system and found to comply with the test, thus demonstrating consistency of the manufacturing process. Some regulatory authorities still require safety tests for the release of each batch/serial and typical tests are described in CFR Title 9 part 113, in this *Terrestrial Manual* and elsewhere. Standard procedures are given for safety tests in mice, guinea-pigs, cats, dogs, horses, pigs, and sheep and are generally conducted using fewer animals than are used in the safety tests required for regulatory approval. Batches/serials are considered satisfactory if local and systemic reactions to vaccination with the batch/serial to be released are in line with those described in the regulatory approval dossier and product literature. Some authorities do not permit batch/serial safety testing in laboratory animals, requiring a test in one of the target species for the product. The European Pharmacopoeia no longer requires a batch safety test in target animal species for the release of vaccine batches/serials nor a general safety test (abnormal toxicity test) in mice or guinea pigs.

2.3. Batch/serial potency test

Batch/serial potency tests, required for each batch/serial prior to release, are designed to correlate with the host animal vaccination–challenge efficacy studies. Potency assays must be properly validated for both live and killed products. For inactivated viral or bacterial products, potency tests may be conducted in laboratory or host animals, or by means of quantitative *in-vitro* methods that have been validated reliably to correlate *in-vitro* quantification of important antigen(s) with *in-vivo* efficacy. The potency of live vaccines is generally measured by means of bacterial counts or virus titration. Recombinant DNA or biotechnology-based vaccines should also be tested. Live genetically modified organisms can be quantified like any other live vaccine by titration, and expressed products of recombinant technology are quantified by *in-vitro* tests, which may be easier to perform compared with tests on naturally grown antigens because of the in-process purification of the desired product.

When testing a live bacterial vaccine for release for marketing, the bacterial count/titre must be sufficiently greater than that shown to be protective in the immunogenicity (efficacy) study to ensure that

at any time prior to the expiry date, the count/titre will be at least equal to that of the batch/serial used in the immunogenicity test. When testing a live viral vaccine for release, the virus titre must, as a rule, be sufficiently greater than that shown to be protective in the immunogenicity test in order to ensure that at any time prior to the expiry date, the titre will be at least equal to that used in the immunogenicity test. Some control authorities specify higher bacterial or viral content than these. It is evident that the appropriate release titre is primarily dependent on the required potency and secondarily dependent on the rate of decay of the bacteria or viruses in the vaccine, as indicated by the stability test.

Standard Requirements have been developed and published by competent authorities for potency testing several vaccines. These tests can be found in CFR Title 9 part 113, in the European Pharmacopoeia, and in this *Terrestrial Manual*.

3. Other tests

3.1. Tests on the finished product

Depending on the form of vaccine being produced, certain tests may be indicated and should be provided as appropriate in the approved documentation of the manufacturing process. These tests may concern: the level of moisture contained in desiccated/lyophilised products, the level of residual inactivant in killed products, the complete inactivation of killed products, pH, the level of preservatives and permitted antibiotics, physical stability of adjuvants, retention of vacuum in desiccated/lyophilised products, and a general physical examination of the final vaccine. A loss of potency may result when residual inactivating agent in a killed liquid product used as a diluent for a desiccated/ lyophilised live fraction reduces the viability of the live organisms because of virucidal or bactericidal activity. Each batch/serial of liquid killed vaccine that is to be used as a diluent for live vaccines must, therefore, be tested for virucidal or bactericidal activity prior to release.

Tests for these purposes may also be found in CFR Title 9 part 113, in EU Directive 2001/82/EC (as amended), in the European Pharmacopoeia, or in this *Terrestrial Manual*.

3.2. Tests on other products

3.2.1. Purity

Purity is determined by testing for a variety of contaminants. Tests to detect contaminants are performed on samples of master seeds, primary cells, master cell stocks (MCS), ingredients of animal origin if not subjected to sterilisation (e.g. fetal bovine serum, bovine albumin, or trypsin).

Procedures used to ensure that fetal or calf serum and other ingredients of bovine origin are free of pestiviruses should be of high concern and well documented. Tests to be used to minimise the risk of impurity vary with the nature of the product, and should be prescribed in the approved documentation of the manufacturing process.

3.2.2. Tests for the detection of TSE agents

As tests for the detection of TSE agents in ingredients of animal origin have not been developed, vaccine manufacturers should document in their Outlines of Production or SOPs the measures they have implemented to minimise the risk of such contamination in ingredients of animal origin. This relies on three principles: first, verification that sources of all ingredients of animal origin in production facilities are from countries recognised as having the lowest possible risk of bovine spongiform encephalopathy; second, that the tissues or other substances used are themselves recognised as being of low or nil risk of containing TSE agents; third, where relevant, that the processes applied to the material have been validated for inactivation of TSE agents in accordance with the *Terrestrial Code*. Methods of production should also document the measures taken to prevent cross contamination of low risk materials by higher risk materials during processing.

MARKET MONITORING

1. Performance monitoring

Holders of relevant regulatory approval or manufacturers are required to maintain an adverse reaction notification system and an effective mechanism for rapid product recall. These should both be subject to audit by regulatory bodies. In many countries, the manufacturer must notify all adverse reactions immediately to the regulatory authority, along with any remedial action taken. An alternative used in some countries is that if at any time, there are indications that raise questions regarding the purity, safety, potency, or efficacy of a product, or if it appears that there may be a problem regarding the preparation, testing or distribution of a product, the manufacturer must immediately notify the regulatory authorities concerning the circumstances and the action taken.

After release of a product, its performance under field conditions should continue to be monitored by competent authorities and by the manufacturer itself. Consumer complaints may serve as one source of information; however, such information should be investigated to determine whether the reported observations are related to the use of the product. Users of veterinary vaccines should be informed of the proper procedures for making their complaints. The manufacturer of the product should be informed of all complaints received by competent authorities. Competent authorities should also ascertain whether they have received other similar complaints for this product and, if so, whether the manufacturer has taken appropriate action. Control laboratories designated by the competent authority may test samples of the batch/serial of product involved, if necessary.

Exporting countries and importing countries should ensure that regulatory approval holders or manufacturers establish a reliable system to monitor adverse reaction notification (vaccinovigilance, post-approval monitoring) is established to identify, at the earliest stage, any serious problems encountered from the use of veterinary vaccines. Vaccinovigilance should be on-going and an integral part of all regulatory programmes for veterinary vaccines, especially live vaccines. The regulatory approval holder or manufacturer plays a big part in the conduct of this continuous overall vaccinovigilance evaluation. When it is determined that a product has a quality defect, immediate action should be taken to notify animal health authorities, to remove the product from the market and, if possible, to inform the end users.

2. Enforcement

National programmes established to ensure the purity, safety, potency, and efficacy of veterinary vaccines must have adequate legal authority to ensure compliance with relevant regulatory approval conditions for the product and other programme requirements. The goal should be to obtain voluntary compliance with established regulatory requirements. However, when violations occur, competent authorities must have adequate legal authority to protect animal and human health and the public interest. Authority for detention, seizure, and condemnation of products found to be worthless, contaminated, dangerous, or harmful is essential for this purpose. Under such authority, product may be detained for a period of time, and if during that time compliance cannot be achieved, competent authorities may seek legal authorisation for seizure and condemnation.

The authority to remove or suspend establishment and/or product regulatory approvals, obtain injunctions, and stop the sale of product is also needed. Civil penalties or criminal prosecution may also be necessary for serious or deliberate violations.

INSPECTION OF PRODUCTION FACILITIES

Establishments that are approved to produce veterinary biologicals should be subject to in-depth inspections of the entire premises by national competent authorities to ensure compliance with the Outline of Production and blueprints and legends, SOPs, or other documentation related to the manufacturing process. These inspections should be carried out on a regular basis and should allow the assessment of the manufacturing sites with regards to GMP standards.

These inspections may include such items as: personnel qualifications; record keeping; general sanitation and laboratory standards; production procedures; operation of sterilisers, pasteurisers, incubators, and refrigerators; filling, desiccating, and finishing procedures; care and control of animals; testing procedures; distribution and marketing; and product destruction.

Details regarding the inspection of production facilities and requirements for inspectorates are described in chapter 2.3.4.

APPENDIX 1.1.8.1.

RISK ANALYSIS FOR BIOLOGICALS FOR VETERINARY USE

GENERAL CONSIDERATIONS

All products, including biologicals for veterinary use, derived from animals have some capacity to transmit animal disease. The level of this capacity depends on the inherent nature of the products, their source, the treatment that they might have undergone, and the purpose for which they are intended. Biologicals for *in-vivo* use in particular will have the highest probability of exposure to animals and as such present the highest risk. Products used for *in-vitro* purposes can introduce disease into animal populations through deliberate or inadvertent use *in vivo*, contamination of other biologicals, or spread by other means. Even products for diagnosis and research have the potential for close contact with animals. Exotic micro-organisms, some highly pathogenic, which may be held for research and diagnostic purposes in countries free from infection or the diseases they cause, could possibly contaminate other biological products.

Veterinary Authorities of importing countries shall make available specific procedural requirements for relevant regulatory approval of biologicals for veterinary use. They may limit supply to registered institutions or *in-vitro* use or for non-veterinary purposes where such assurance cannot be provided.

*
* *

APPENDIX 1.1.8.2.

RISK ANALYSIS FOR VETERINARY VACCINES

INTRODUCTION

Risk analysis for veterinary vaccines has to be founded on the principles of quality assurance, which includes quality control, in the production of veterinary vaccines. These recommendations are focused mainly on the risk related to the contamination of vaccines by infectious agents particularly in regard to the risk of importing exotic diseases. The major risk of introducing a disease into a country is through importation of live animals or animal products and rarely through veterinary vaccines. Veterinary vaccines can however be contaminated by disease agents if master seeds, strains, cell cultures, animals or ingredients of animal origin such as fetal calf serum used in production are contaminated or if cross contamination occurs during the production process.

PRINCIPLES

Exporting countries and importing countries should agree on a system of classification of risks associated with veterinary vaccines taking into account factors such as purification procedures which have been applied.

Exporting countries and importing countries should agree on risk analysis models to address specific issues and products. Such risk analysis models should include a scientific risk assessment and formalised procedures for making risk management recommendations and communicating risk. The regulation of veterinary vaccines should include the use of either qualitative or quantitative models.

Risk analysis should be as objective and transparent as possible. Step risk and scenario tree methods should be used in risk assessment whenever appropriate, as they identify the critical steps in the production and use of the products where risks arise and help to characterise those risks.

The same conclusions about risk analysis may be reached by differing methods. Where methods may differ in countries, the concept of equivalence should apply wherever possible and the methods should be validated to ensure they are of comparable sensitivity.

MANUFACTURING PRACTICES

The manufacture of veterinary vaccines has special characteristics which should be taken into consideration when implementing and assessing the quality assurance system. Due to the large number of animal species and related pathogenic agents, the variety of products manufactured is very wide and the volume of manufacture is often low; hence, work on a group basis is common. Moreover, because of the very nature of this manufacture (cultivation steps, lack of terminal sterilisation, etc.), the products must be particularly well protected against contamination and cross contamination. The environment must also be protected especially when the manufacture involves the use of pathogenic or exotic biological agents and the worker must be particularly well-protected when the manufacture involves the use of biological agents pathogenic to man.

These factors, together with the inherent variability of immunological products, means that the role of the quality assurance system is of the utmost importance. It is important that vaccines should be manufactured in accordance with a recognised codified system that includes specifications regarding equipment, premises, qualification of personnel as well as quality assurance and regular inspections.

A commonly agreed system of facility inspection carried out by qualified and specialised inspectors must be in place to assure confidence.

INFORMATION TO BE SUBMITTED WHEN APPLYING FOR RELEVANT REGULATORY APPROVAL IN THE IMPORTING COUNTRY

The manufacturer or Veterinary Authority of the exporting country should make available to the importing country the pharmacopoeia it uses. For the importing country it is necessary to have documented both the quality control methods used and the source of each batch of starting materials. The key steps of the manufacturing process of veterinary vaccines should be described in detail to help risk analysis. Risk analysis has to be focused on the quality and safety parts of the application file. Laboratory safety testing should cover target and non-target organisms to obtain sufficient biological data. All test procedures used should correspond with the state of scientific knowledge at the time and should be validated.

The description of the method of preparation of the finished product should include an adequate characterisation of the substances needed to prepare the working seeds, the description of the treatments applied to starting materials to prevent contamination, and a statement of the stages of manufacture at which sampling is carried out for process control tests.

The results of control tests during production and on finished product, as well as the sensitivity of these tests, have to be available for risk analysis. The stepwise procedures of the control tests should also be available.

CATEGORISATION OF VETERINARY VACCINES

To assist in risk analysis, countries should establish a system of categorisation of veterinary vaccines taking into account criteria such as pathogens used as active ingredients, their inherent characteristics and the risk they pose.

In case of live vectored vaccines, the safety of the vector to the targeted and non-targeted species and to human beings must be assessed. Special attention should be paid to potential tissue tropism or host range modification of the recombinant.

VACCINOVIGILANCE

Exporting countries and importing countries should ensure that a reliable system of vaccinovigilance (post-approval monitoring) is established to identify, at the earliest stage, any serious problems encountered from the use of veterinary vaccines. Vaccinovigilance should be ongoing and an integral part of all regulatory programmes for veterinary vaccines, especially live vaccines.

RISK COMMUNICATION

Reliable data in support of applications submitted in importing countries should be provided by the manufacturer or the Veterinary Authority of the exporting country. Relevant data on risk analysis, changes in animal health situations and vaccinovigilance should be shared by Veterinary Authorities on a continuous basis.

CHAPTER 1.1.9.

TESTS FOR STERILITY AND FREEDOM FROM CONTAMINATION OF BIOLOGICAL MATERIALS INTENDED FOR VETERINARY USE

INTRODUCTION

The international trade-related movements of biological materials intended for veterinary use are subject to restrictions imposed to minimise the spread of animal and human pathogens. Countries may impose requirements for proof-of-freedom testing before allowing the regulated importation of materials of animal derivation and substances containing such derivatives. Where chemical or physical treatments are inappropriate or inefficient, or where evidence of the effectiveness of the treatment is lacking, there may be general or specific testing requirements imposed by authorities of countries receiving such materials. This chapter provides guidance on the approach to such regulated testing, particularly as might be applied to the movement of vaccine master seed and master cell stocks, and to related biological materials used in manufacturing processes. The term seed stocks is used when testing live products, for killed products the preferred reference is master cell stocks. While the onus for ensuring safety of a product remains with the manufacturer and may be regulated by therapeutic guidelines, this chapter provides procedures that are designed in particular to minimise the risk of undetected contaminants in veterinary therapeutics and biological reagents causing the cross-border spread of agents of concern to particular importing countries. Control of contamination with transmissible spongiform encephalopathy (TSE) agents is not covered in this chapter because testing and physical treatments cannot be used to ensure freedom from these agents.

Sterility is defined as the absence of viable microorganisms, which for the purpose of this chapter, includes viruses. It should be achieved using aseptic techniques and validated sterilisation methods, including heating, filtration, chemical treatments, and irradiation that fits the intended purpose. Freedom from contamination is defined as the absence of specified viable microorganisms. This may be achieved by selecting materials from sources shown to be free from specified microorganisms and by conducting subsequent procedures aseptically. Adequate assurance of sterility and freedom from contaminating microorganisms can only be achieved by proper control of the primary materials used and their subsequent processing. Tests on intermediate products are necessary throughout the production process to check that this control has been achieved.

Biological materials subject to contamination that cannot be sterilised before or during use in vaccine production, such as ingredients of animal origin, e.g. serum and trypsin, primary and continuous cells and cell lines, and viral or bacterial seed stocks, etc., should be tested for viable extraneous agents before use. Assays to detect viral contaminants, if present, can be achieved by culture methods supported by cytopathic effects (CPE) detection, fluorescent antibody techniques and other suitable methods such as polymerase chain reaction (PCR) and enzyme-linked immunosorbent assay (ELISA). As is explained in more detail in this chapter care must be taken when using PCR and ELISA techniques for detection as such tests do not distinguish viable from non-viable agent detection.

Avian materials and vaccines are required to be inoculated on to primary avian cell cultures or eggs for the detection of avian viruses. A combination of general tests, for example to detect haemadsorbing, haemagglutinating and CPE-causing viruses and specific procedures aimed at the growth and detection of specific viruses is recommended to increase the probability of detection. Assays to detect other contaminants, such as bacteria, fungi, protozoa, rickettsia and mycoplasma are also described.

Procedures applied should be validated and found to be "fit for purpose" following Chapter 1.1.6 Validation of diagnostic assays for infectious diseases of terrestrial animals*, where possible.*

It is the responsibility of the submitter to ensure a representative selection and number of items to be tested. The principles of Appendix 1.1.2.1 Epidemiological approaches to sampling: sample size calculations *of Chapter 1.1.2* Collection, submission and storage of diagnostic specimens apply. *Adequate transportation is described in Chapter 1.1.2 and Chapter 1.1.3* Transport of biological materials*.*

A. AN OVERVIEW OF TESTING APPROACHES

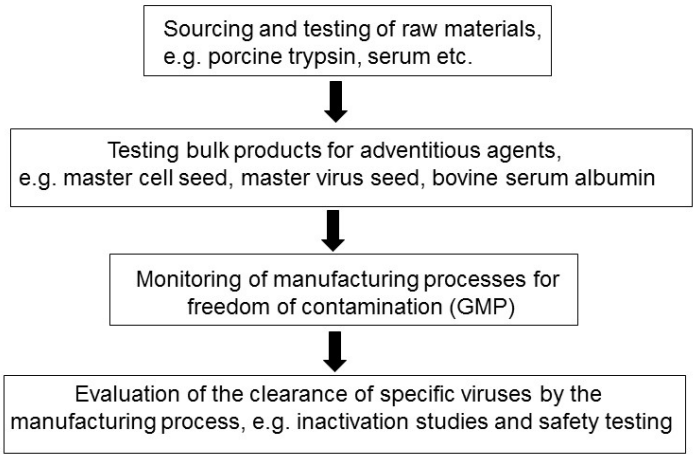
1. Primary materials must be collected from sources shown to be free from contamination and handled in such a way as to minimise contamination and the opportunities for any contaminants to multiply (Figure 1).

2. Materials that are not sterilised and those that are to be processed further after sterilisation must be handled aseptically. Such materials will require further assessment of freedom of contaminants at certain stages of production to assure freedom of adventitious agents.

3. Materials that can be sterilised without their biological activities being affected unduly must be sterilised by a method effective for the pathogens of concern. The method must reduce the level of contamination to be undetectable, as determined by an appropriate sterility test study. (See Section D.1. below). If a sterilisation process is used, it shall be validated to demonstrate that it is fit for purpose. Suitable controls will be included in each sterilisation process to monitor efficiency.

4. The environment in which any aseptic handling is carried out must be maintained in a clean state, protected from external sources of contamination, and controlled to prevent internal contamination. Rules governing aseptic preparation of vaccines are documented in Chapter 2.3.3 *Minimum requirements for the organisation and management of a vaccine manufacturing facility*.

Figure 1. Testing algorithm for vaccine production.



Some procedures have been properly validated and found to be "fit for purpose", whilst others may have undergone only limited validation studies. For example, methods for bacterial and fungal sterility have not been formally validated although they have been used for many years. In particular, the *in-vivo* and cell culture methods have essentially unknown sensitivity and specificity (Sheets *et al*., 2012) though there is an accepted theoretical sensitivity of 1 colony-forming unit (CFU). For example, an evaluation of methods to detect bovine and porcine viruses in serum and trypsin based on United States (of America) Code of Federal Regulations, Title 9 (9CFR) revealed gaps in sensitivity, even within virus families (Marcus-Secura *et al*., 2011). It is therefore important to interpret results in the light of specific conditions of cultures employed and considering sensitivity and specificity of detection systems.

Newer, more sensitive methods such as molecular assays may afford the ability to detect contaminants, which may not be successfully amplified in traditional culturing systems. The detection range can be broadened by using

family specific primers and probes if designed appropriately. However, most, if not all such new tests are also able to detect evidence for non-infectious contaminants, such as traces of nucleic acid from inactivated contaminants. Follow-up testing would be required to determine the nature of the contaminant, for example, non-infectious nucleic acid or infectious virus. Attempts at virus isolation or sequencing may remedy this. Note: molecular assays if not designed as fit for purpose may miss detection of contaminating agents or lack sensitivity to do so (Hodinka, 2013).

More recently metagenomic high throughput sequencing (HTS) workflows have shown potential for quality control of biological products (van Borm *et al*., 2013) and vaccines (Baylis *et al.,* 2011; Farsang & Kulcsar, 2012; Neverov & Chumakov, 2010; Onions & Kolman, 2010; Victoria *et al*., 2010) in particular for the identification and characterisation of unexpected highly divergent pathogen variants (Miller *et al*., 2010; Rosseel *et al*., 2011) that may remain undetected using targeted diagnostic tests. Nevertheless, targeted assays, e.g. amplification in cell culture followed by polymerase chain reaction (PCR) may be superior to HTS for specific agent detection (Wang *et al*., 2014) due to lack of sensitivity of HTS at this time. Similarly, recent improvements in protein and peptide separation efficiencies and highly accurate mass spectrometry have promoted the identification and quantification of proteins in a given sample. Most of these new technologies are broad screening tools, limited by the fact that they cannot distinguish between viable and non-viable organisms.

B. LIVING VIRAL VACCINES FOR ADMINISTRATION BY INJECTION

1. Materials of animal origin shall be (a) sterilised, or (b) obtained from healthy animals that, in so far as is possible, should be shown to be free from pathogens that can be transmitted from the species of origin to the species to be vaccinated, or any species in contact with them by means of extraneous agents testing.

2. Seed lots of virus, any continuous cell line and biologicals used for virus growth shall be shown to be free from viable bacteria, fungi, mycoplasmas, protozoa, rickettsia, extraneous viruses and other pathogens that can be transmitted from the species of origin to the species to be vaccinated or any species in contact with them.

   For the production of vaccines in embryonated chicken eggs and the quality control procedures for these vaccines, it is recommended (required in many countries) that eggs from specific pathogen-free birds should be used.

3. Each batch of vaccine shall pass tests for freedom from extraneous agents that are consistent with the country's requirements for accepting the vaccine for use. Published methods that document acceptable testing procedures in various countries include: (US) Code of Federal Regulations (2015); European Pharmacopoeia (2014); European Commission (2006); World Health Organization (WHO) (1998; 2012) and Department of Agriculture (of Australia) (2013).

4. Tests for sterility shall be appropriate to prove that the vaccine is free from extraneous viruses, bacteria including rickettsia and mycoplasmas, fungi, and protozoa. Each country will have particular requirements as to what agents are necessary to exclude for and what procedures are acceptable. Such tests will include amplification of viable extraneous agents using cell culture that is susceptible to particular viruses of the species of concern, tests in embryonated eggs, bacterial, mycoplasma and fungal culturing techniques and, where necessary and possible, tests involving animal inoculation. PCR, fluorescence antibody test (FAT), presence of colonies or cytopathic effects (CPE) and enzyme-linked immunosorbent assay (ELISA) will be used for detection purposes after amplification using culturing techniques. If *in-vitro* or *in-vivo* amplification of the target agent is not possible, direct PCR may be useful if validated for this purpose.

C. LIVING VIRAL VACCINES FOR ADMINISTRATION THROUGH DRINKING WATER, SPRAY, OR SKIN SCARIFICATION

1. Section B applies.

2. A limited number of contaminating, non-pathogenic bacteria and fungi may be permitted (see Section I.2.2 *General Procedure for testing live viral vaccines produced in eggs and administered through drinking water, spray, or skin scarification for the presence of bacteria and fungi*).

D. INACTIVATED VIRAL VACCINES

1. Each batch of vaccine shall pass a test for inactivation of the vaccinal virus and should include inactivation studies on representative extraneous agents if the virus seed has not already been tested and shown to be free from extraneous agents. An example of a simple inactivation study could include assessment of the titre of live vaccine before and after inactivation and assessing the $\log_{10}$ drop in titre during the inactivation process. This would give an indication of the efficacy of the inactivation process. There is evidence that virus titration tests may not have sufficient sensitivity to ensure complete inactivation. In these circumstances, a specific innocuity test would need to be developed and validated to be fit for increased sensitivity. To increase sensitivity more than one passage would be required depending on the virus of concern. An example of this approach can be found at:
https://www.aphis.usda.gov/animal_health/vet_biologics/publications/memo_800_117.pdf.

2. If studies on representative extraneous agents are required, then spiking inactivated vaccine with live representative agents and following the example of an inactivation study as in D.1 above would be useful. The inactivation process and the tests used to detect live virus after inactivation must be validated and shown to be suitable for their intended purpose.

   In addition, each country may have particular requirements for sourcing or tests for sterility as detailed in Section B above.

E. LIVING BACTERIAL VACCINES

1. Section B applies.

2. Seed lots of bacteria shall be shown to be free from other bacteria as well as fungi and mycoplasmas, protozoa, rickettsia, and extraneous viruses. Agents required for exclusion will be dependent on the country accepting the vaccine for use. Use of antibiotics to 'inactivate' the living bacterial seed or vaccine prior to exclusion of viruses and fungi is recommended to ensure testing in culture is sensitive. Interference testing is recommended to ensure that the antibiotics used do not affect the growth of the extraneous virus or fungi that is being excluded.

3. Due to the difficulties and reduced sensitivity in exclusion of extraneous bacteria and some mycoplasma, protozoa, and rickettsia from high-titred seed lots of bacteria, the use of narrow-range antibiotics aimed specifically at reducing seed lot bacteria is recommended if antibiotics do not affect the growth of bacteria being excluded. The optimal concentration of antibiotics can be determined in a dilution experiment such as documented in 9CFR Section 113.25(d). Other methods of exclusion of extraneous bacteria from bacterial seeds may include filtering for size exclusion such as removing bacteria seed to look for mycoplasma contamination and use of selective culturing media. Such processes would require validation to ensure the process does not affect the sensitivity of exclusion of extraneous agents of concern.

4. Direct PCR techniques may be useful when culturing processes fail to be sensitive in detecting extraneous bacteria from live bacterial seeds or vaccines.

F. INACTIVATED BACTERIAL VACCINES

1. Section D applies. It should not be necessary to test for extraneous viruses that would not grow in bacteriological culture media as long as freedom from contamination of all starting materials can be assured. Complete inactivation of the vaccinal bacteria should be demonstrated by means of titration and innocuity tests – in some cases general bacterial sterility testing (Section I.2.1) may suffice.

G. SERA AND DIAGNOSTIC AGENTS FOR ADMINISTRATION TO ANIMALS

1. Section B.1 applies for non-inactivated sera.

2. Some countries require quarantine, health certification, and tests for specific diseases to be completed for all serum donor animals, for example, 9CFR (2015) and Australian Quarantine Policy and Requirements for the Importation of Live and Novel Veterinary Bulk and Finished Vaccines (1999).

3. It is recommended that each batch of non-inactivated serum be assessed for viable extraneous agents, including mycoplasma. Each batch of serum shall pass a test for freedom from extraneous agents. Suitable test methods have been published for various countries, for example, European Pharmacopoeia (2014); 9 CFR (2015) and Australian Quarantine Policy and Requirements for the Importation of Live and Novel Veterinary Bulk and Finished Vaccines (1999) and Department of Agriculture (of Australia) (2013).

4. Inactivated serum, Section D applies.

5. Section B or D may apply if a virus is used in the production of the diagnostic agent; Section E or F may apply if a bacterium is used.

H. EMBRYOS, OVA, SEMEN

Special precautions must be taken with relation to the use of embryos, ova, semen (Hare, 1985). Most countries will have regulatory guidelines for import of these biologicals for veterinary use. Such guidelines can be found at various websites such as the European Commission, FAO and though many such guidelines give more detail in regard to the food safety aspect.

I. PROTOCOL EXAMPLES

1. General procedures

In principle, proposed testing represents an attempted isolation of viable agents in culturing systems normally considered supportive of the growth of each specified agent or group of general agents. After amplification, potential pathogens can be detected further by sensitive and specific diagnostic tests such as FAT or PCR if required. General detection systems can include haemabsorbance and CPE by immunohistochemistry staining methods. The example procedures for sterility testing and general detection of viable bacteria, mycoplasma, fungi, and viruses described below are derived from standards such as the 9CFR (2015), European Pharmacopoeia (2014), European Commission (2006), WHO (1998; 2012).

Individual countries or regions should adopt a risk-based approach to determine the appropriate testing protocols based on their animal health status. As well as applying general testing procedures documented in national or regional standards as mentioned above, it may be necessary to apply rigorous exclusion testing for specific agents that are exotic to the particular country or region.

General procedures will not necessarily detect all extraneous agents that may be present in biological material; however, they are useful as screening tests. Some examples of agents that may require specific methods for detection in biologicals refer to Table 1 below. Procedures documented in the Review of Published Tests to Detect Pathogens in Veterinary Vaccines Intended for Importation into Australia (2013) available from the Department of Agriculture and Water Resources, Australia are able to address such agents in offering sensitive testing approaches based on reputable publications.

Exclusion of specific agents requires procedures that maximise sensitivity by providing ideal amplification and detection of the pathogen in question. Extraneous agents, such as Maedi Visna virus, bovine immunodeficiency virus, *Trypanosoma evansi* and porcine respiratory coronavirus are difficult to culture even using the most sensitive approaches. In these circumstances, application of molecular assays directly to the biological material in question to assess the presence of nucleic acid from adventitious agents offers an alternative. Refer to Table 1. Consideration must be noted as described in Section A.6 as non-viable agents may also be detected using this procedure.

Table 1 gives some examples of causative infectious agents that may be present in animal biologicals intended for veterinary use. This is not an exhaustive list of agents of concern or by any means required for exclusion by every country, they are just examples of infectious agents that are not culturable using general culturing procedures and require a more specific detection process by means of the indirect fluorescent antibody test, PCR or ELISA, where applicable. Notably, some subtypes of an agent type may be detectable by general methods, and some may require

specialised testing for detection. For example, bovine adenovirus subgroup 1 (serotypes 1, 2, 3 and 9) can be readily isolated using general methods (Vero cells) however bovine adenovirus subgroup 2 (serotypes 4, 5, 6, 7, 8 and 10) are not readily isolated and required specialised methods for isolation.

Table 1. Some examples of infectious agents of veterinary importance that require specialist culturing and detection techniques

Rotaviruses	Pestiviruses (non-CPE)	Turkey rhinotracheitis
Porcine epidemic diarrhoea virus	Bluetongue virus	*Brucella abortus*
Porcine circoviruses (PCV 1, 2)	Swine pox virus	Rickettsias
Swine/equine influenza, some strains	Some adenoviruses	Protozoa
Bovine respiratory syncytial virus	Rabies virus	Some fungi (e.g. *Histoplasma*)

2. Detection of bacteria and fungi

2.1. General procedure for assessing the sterility of viable bacteria and fungi

Standard tests for detecting extraneous bacteria and fungi (sterility testing) in raw materials, master cell stocks, or final product are the membrane filtration test or the direct inoculation sterility test.

For the membrane filtration technique, a filter having a nominal pore size not greater than 0.45 μm and a diameter of at least 47 mm should be used. Cellulose nitrate filters should be used if the material is aqueous or oily; cellulose acetate filters should be used if the material is strongly alcoholic, oily or oil-adjuvanted. Immediately before the contents of the container or containers to be tested are filtered, the filter is moistened with 20–25 ml of Diluent A or B.

2.1.1. Diluent A

Diluent A is for aqueous products or materials. Dissolve 1 g peptic digest of animal tissue in water to make 1 litre, filter, or centrifuge to clarify, adjust the pH to 7.1 ± 0.2, dispense into containers in 100 ml quantities, and sterilise by steam.

2.1.2. Diluent B

Diluent B is for oil-adjuvanted products or materials: Add 1 ml polysorbate 80 to 1 litre Diluent A, adjust the pH to 7.1 ± 0.2, dispense into containers in 100 ml quantities, and sterilise by steam.

If the biological being tested has antimicrobial properties, the membrane is washed three times after sample application with approximately 100 ml of the appropriate diluent (A or B). The membrane is then transferred whole to culture media, aseptically cut into equal parts and placed in media, or the media is transferred to the membrane in the filter apparatus. If the test sample contains merthiolate as a preservative, fluid thioglycollate medium (FTM) is used and the membranes are incubated at both 30–35°C and 20–25°C. If the test sample is a killed biological without merthiolate preservative, FTM is used at 30–35°C and soybean casein digest medium (SCDM) at 20–25°C. If the sample tested is a live viral biological, SCDM is used at both incubation temperatures. It has been suggested that sulfite-polymyxin-sulfadiazine agar be used to enhance the detection of *Clostridium* spp. when the membrane filtration technique is used (Tellez *et al*., 2005).

If direct inoculation of culture media is chosen, a sterile pipette or syringe and needle are used to aseptically transfer the biological material directly into liquid media. If the biological being tested has antimicrobial properties, the ratio of the inoculum to the volume of culture medium must be determined before the test is started, for example as explained in 9CFR 113.25(d) and detailed testing procedures can be found for example in supplemental assay method (SAM) 903. To determine the correct medium volume to negate antimicrobial activity, 100 CFU of the control microorganisms listed in Table 2 are used. If the test sample contains merthiolate as a preservative, FTM is used in test vessels incubated at both 30–35°C and 20–25°C. Growth should be clearly visible after an appropriate incubation time (see Section I.2.1.3 *Growth promotion and test interference*). If the test sample is a killed biological without merthiolate, or a live bacterial biological, FTM is used at 30–35°C and SCDM at 20–25°C. If the test sample is a live viral biological, SCDM is used at both incubation temperatures. If the inactivated bacterial vaccine is a clostridial biological, or contains a clostridial component, the use of FTM with 0.5% added

beef extract (FTMB) in place of FTM is preferred. It may also be desirable to use both FTM and SCDM for all tests.

Table 2. Some American Type Culture Collection[1] strains with their respective medium and incubation conditions

Medium	Test microorganism	Incubation	
		Temperature (°C)	Conditions
FTM	*Bacillus subtilis* ATCC # 6633	30–35	Aerobic
FTM	*Candida krusei* ATCC # 6258	20–25	Aerobic
SCDM	*Bacillus subtilis* ATCC # 6633	30–35	Aerobic
SCDM	*Candida krusei* ATCC # 6258	20–25	Aerobic
FTMB	*Clostridium sporogenes* ATCC # 11437	30–35	Anaerobic
FTMB	*Staphylococcus aureus* ATCC #6538	30–35	Aerobic

For both membrane filtration and direct inoculation sterility tests, all media are incubated for no fewer than 14 days. At intervals during incubation, and after 14 days' incubation, the test vessels are examined for evidence of microbial growth. Microbial growth should be confirmed by subculture and Gram stain.

2.1.3. Growth promotion and test interference

The sterility of the media should be confirmed by incubating representative containers at the appropriate temperature for the length of time specified for each test.

The ability of the culture media to support growth in the presence and absence of product, product components, cells, seeds, or other test material should be validated for each product to be tested, and for each new batch or lot of culture media for example as outlined in 9CFR 113.25(b). Detailed testing procedures can be found for example in SAMs 900-902.

To test for ability to support growth in the absence of the test material, media should be inoculated with 10–100 viable control organisms of the suggested ATCC strains listed in Table 2 and incubated according to the conditions specified.

To test for ability of the culture media to support growth in the presence of the test material, containers should be inoculated simultaneously with both the test material and 10–100 viable control organisms. The number of containers used should be at least one-half the number used to test the product or product component. The test media are satisfactory if clear evidence of growth of the control organisms appears in all inoculated media containers within 7 days. In the event that growth is evident, the organism should be identified to confirm that it is the organism originally added to the medium. The sterility test is considered invalid if any of the media show inadequate growth response, or if the organism recovered, is not the organism used to inoculate the material.

If the material being tested renders the medium turbid so that the presence or absence of microbial growth cannot be readily determined by visual examination, 14 days after the beginning of incubation transfer portions (each not less than 1 ml) of the medium to fresh vessels of the same medium and then incubate the original and transfer vessels for not less than 4 days.

2.2. General procedure for testing live viral vaccines produced in eggs and administered through drinking water, spray, or skin scarification for the presence of bacteria and fungi

Each batch of final container biological should have an average contamination of not more than one bacterial or fungal colony per dose for veterinary vaccines. From each container sample, each of two Petri dishes are inoculated with vaccine equal to ten doses if the vaccine is recommended for poultry, or one dose if recommended for other animals. To each plate 20 ml of brain–heart infusion agar are added

1 American Type Culture Collection, 10801 University Boulevard, Manassas, Virginia 20110-2209, USA.

containing 0.007 IU (International Units) of penicillinase per ml. One plate should be incubated at 30–35°C for 7 days and the other at 20–25°C for 14 days. Colony counts are made at the end of each incubation period. An average colony count of all the plates representing a batch should be made for each incubation condition. If the average count at either incubation condition exceeds one colony per dose in the initial test, one retest to rule out faulty technique may be conducted using double the number of unopened final containers. If the average count at either incubation condition of the final test for a batch exceeds one colony per dose, the batch of vaccine should be considered unsatisfactory.

2.3. General procedure for testing seed lots of bacteria and live bacterial biologicals for purity

Each seed lot of bacteria or batch of live bacterial biological should be tested for purity by inoculation of SCDM, which is incubated at 20–25°C for 14 days, and FTM, which is incubated at 30–35°C for 14 days. A sterile pipette or syringe and needle is used to aseptically transfer the quantity of biological directly into the two types of culture medium. The minimum ratio of inoculum to culture medium is 1/15.

If the inoculum or growth of the bacterial vaccine renders the medium turbid so that the absence of atypical microbial growth cannot be determined by visual examination, subcultures should be made from all turbid tubes on day 3 through to day 11. Subculturing is done by transferring 0.1–1.0 ml to differential broths and agar and incubating for the balance of the 14-day period. Microscopic examination by Gram stain should also be done.

If no atypical growth is found in any of the test vessels when compared with a positive control included in the test, the lot of biological may be considered satisfactory for purity. If atypical growth is found but it can be demonstrated by control that the media or technique were faulty, then the first test may be repeated. If atypical growth is found but there is no evidence invalidating the test, then a retest may be conducted. Twice the number of biological containers and test vessels of the first test are used in the retest. If no atypical growth is found in the retest, the biological could be considered to be satisfactory for purity but the results from both the initial and retest should be reported for assessment by the individual countries relevant regulatory agency. If atypical growth is found in any of the retest vessels, the biological is considered to be unsatisfactory for purity. If, however, it can be demonstrated by controls that the media or technique of the retest were faulty, then the retest may be repeated.

2.4. An example of a procedure for exclusion where general testing is not sufficient for detection of *Brucella abortus*

It should be confirmed that each batch of culture medium supports the growth of *B. abortus* by inoculating plates and flasks of biphasic medium with a known number of cells (around 100) of the fastidious *B. abortus* biovar 2. If the media supports the growth of this biotype it will support all other biovars.

Inoculate 1.0 ml of prepared master or working viral or cell seed material (not containing antibiotics) by inoculating 50 µl of the test product into each of 10 flasks containing biphasic medium. At the same time 10 plates of serum dextrose agar (SDA) are inoculated with 50 µl of inoculum and spread with a sterile bent glass Pasteur pipette or hockey stick. An un-inoculated serum dextrose agar plate and a biphasic flask are also set up at the same time as negative controls.

For assessment of inhibitory substances 50 µl of previously prepared master or working viral or cell seed material and 10–100 CFU of *B. abortus* are inoculated on to duplicate SDA plates. Positive controls are prepared by inoculating 10–100 CFU of *B. abortus* on to duplicate SDA plates.

All plates and flasks are incubated at 37°C in a 5–10% CO_2 environment. Plates are incubated with the agar uppermost and flasks with the agar slope vertical. Flasks are incubated with the cap loose.

Plates are checked for growth of colonies at days 4 and 8 of incubation. The biphasic medium is examined every 4 to 7 days for 28 days. After each examination of the flasks, they are tilted so that the liquid phase runs over the solid phase, then righted and returned to the incubator.

During the incubation period, SDA plates with positive control and test material are visually compared with plates with the positive control only and if there is no inhibition of growth of the organism in the

presence of the test material, the interference testing test is successful and testing can be assured to be sensitive.

Any signs of growth of suspicious contaminating microorganisms on SDA plates, cloudiness or colonies in biphasic flasks require follow-up testing by PCR to confirm whether *B. abortus* is present.

2.5. An example of a general procedure for detection of *Salmonella* contamination

Each batch of live virus biological made in eggs should be free from contamination with *Salmonella*. This testing must be done before bacteriostatic or bactericidal agents are added. Five samples of each batch should be tested; 5 ml or one-half of the container contents, whichever is the lesser, of the sample should be used to inoculate 100 ml of tryptose broth and tetrathionate broth. The inoculated broths should be incubated for 18–24 hours at 35–37°C. Transfers from these broths should be made on to MacConkey and *Salmonella–Shigella* agar, incubated for 18–24 hours, and examined. If no growth typical of *Salmonella* is noted, the agar plates should be incubated an additional 18–24 hours and again examined. If colonies typical of *Salmonella* are observed, further subculture on to suitable differential media should be made for positive identification. Sensitive PCR tests are available for the detection of *Salmonella* spp. in cultured material. If *Salmonella* is detected, the batch is determined to be unsatisfactory.

3. Detection of *Mycoplasma* contamination

3.1. An example of a general procedure for detecting *Mycoplasma* contamination

Each batch of live viral vaccine, each lot of master seed virus (MSV), each lot of primary and master cell stock (MCS), and all ingredients of animal origin not steam-sterilised should be tested for the absence of mycoplasmas. Solid and liquid media that will support the growth of small numbers of test organisms, such as typical contaminating organisms *Acholeplasma laidlawii*, *Mycoplasma arginini*, *M. fermentans*, *M. hyorhinis*, *M. orale*, and *M. synoviae* should be used. The nutritive properties of the solid medium should be such that no fewer than 100 CFU should occur with each test organism when approximately 100–200 CFUs are inoculated per plate. An appropriate colour change should occur in the liquid media when approximately 20–40 CFUs of each test organism are inoculated. The ability of the culture media to support growth in the presence of product should be validated for each product to be tested, and for each new batch or lot of culture media.

One sample of each lot of vaccine, e.g. MSV or MCS, should be tested. Four plates of solid medium are inoculated with 0.25 ml of the sample being tested, and 10 ml of the sample inoculated into 100 ml of the liquid medium. An alternative is to inoculate each of the plates with 0.1 ml and to inoculate 100 ml of liquid medium with 1 ml of the sample being tested. Two plates are incubated at 35–37°C aerobically (an atmosphere of air containing 5–10% CO_2 and adequate humidity) and two plates are incubated anaerobically (an atmosphere of nitrogen containing 5–10% CO_2 and adequate humidity) for 14 days. On day 3 or day 4 after inoculation, 0.25 ml from the liquid media are subcultured on to two plates of solid media. One plate is incubated aerobically and the second anaerobically at 35–37°C for 14 days. The subculture procedure is repeated on day 6, 7, or 8 and again on day 13 or 14. An alternative method is to subculture on days 3, 5, 10, and 14 on to a plate of solid medium. All the subculture plates are incubated for 10 days except for the 14-day subculture, which is incubated for 14 days. Liquid media is observed every 2–3 days and, if any colour change occurs, has to be subcultured immediately.

3.2. Interpretation of *Mycoplasma* test results

At the end of the incubation period (total 28 days), examine all the inoculated solid media microscopically for the presence of mycoplasma colonies. The test sample passes the test if the growth of mycoplasma colonies has occurred on the positive controls, and if growth has not occurred on any of the solid media inoculated with the test material. If at any stage of the test, more than one plate is contaminated with bacteria or fungi, or is broken, the test is invalid and should be repeated. If mycoplasma colonies are found on any agar plate, a suitable confirmatory test on the colonies should be conducted, such as PCR. Some mycoplasmas cannot be cultivated, in which case the MSV and MCS have to be tested using an indicator cell line such as Vero cells, DNA staining, or PCR methods.

Further detailed procedures can be found in Veterinary Medicinal Products, VICH GL34: http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2013/03/WC500140352.pdf

and USDA SAM 910: https://www.aphis.usda.gov/animal_health/vet_biologics/publications/910.pdf, (both accessed 4 July 2022.)

3.3. An example of a specific procedure for exclusion of *Mycoplasma mycoides* subsp. *mycoides* type from biologicals used in production of veterinary vaccines

Prior to beginning testing it is necessary to determine that each batch of media promotes the growth of *M. mycoides* subsp. *mycoides* (*Mmm*) type strain PG1. General mycoplasma broth and agar are used but contain porcine serum as a supplement. Each batch of broth and agar is inoculated with 10–100 CFU of *Mmm*. The solid medium is suitable if adequate growth of *Mmm* is found after 3–7 days' incubation at 37°C in 5–10% CO_2. The liquid medium is suitable if the growth on the agar plates subcultured from the broth is found by at least the first subculture. If reduced growth occurs another batch of media should be obtained and retested.

1 ml of cell or virus seed to be tested is inoculated into 9 ml of the liquid medium and 100 µl on to solid mycoplasma agar. The volume of the product is inoculated so that it is not more than 10% of the volume of the medium. The liquid medium is incubated at 37°C in 5–10% CO_2 and 100 µl of broth is subcultured on to agar at days 7, 14 and 21. The agar plates are incubated at 37°C in 5–10% CO_2 for no fewer than 14 days, except those corresponding to day 21 subculture, which are incubated for 7 days. An un-inoculated mycoplasma broth and agar plate are incubated as negative controls. For assessment of inhibitory substances, inoculate 1 ml of sample to be tested into 9 ml of the liquid medium and 100 µl on to solid medium and add 10–100 CFU of *Mmm* to each. Prepare positive control by inoculating 9 ml of mycoplasma broth and a mycoplasma agar plate with 10–100 CFU of *Mmm*. Incubate as for samples and negative controls.

During incubation time, visually compare the broth of the positive control with sample present with the positive control broth and, if there is no inhibition of the organism either the product possesses no antimicrobial activity under the conditions of the test, or such activity has been satisfactorily eliminated by dilution. If no growth or reduced growth of *Mmm* is seen in the liquid and solid medium with test sample when compared with the positive control, the product possesses antimicrobial activity, and the test is not satisfactory. Modifications of the conditions to eliminate the antimicrobial activity and repeat test are required.

If antimicrobial activity is present it is necessary to dilute the test product further. Repeat the test above using 1.0 ml of sample in 39 ml of mycoplasma broth and then inoculate with 10–100 CFU of *Mmm* and incubate as above. All broths and plates are examined for obvious evidence of growth. Evidence of growth can be determined by comparing the test culture with the negative control, the positive control, and the inhibition control.

If evidence of microbial growth is found in the test samples the contaminating bacterium will be identified and confirmed as *Mmm* by PCR assay.

4. Detection of rickettsia and protozoa

There are no general test procedures for exclusion of rickettsia or protozoa. Procedures to exclude specific agents of concern such as *Coxiella burnetti* (Q fever), *Ehrlichia canis, Trypanosoma evansi* and *Babesia caballi* can be found for example, in the Review of Published Tests to detect pathogens in veterinary vaccines Intended for Importation into Australia (Department of Agriculture [of Australia] [2013]). The review is based on the reading and interpretation of applicable published papers from reputable journals and are regarded as examples of sensitive methods for detection of specified agents.

4.1. An example of protocol based on published methods for exclusion of *Babesia caballi* and *Theileria equi*

Babesia caballi and *Theileria equi* can be cultured *in vitro* in 10% equine red blood cells (RBC) in supportive medium supplemented with 40% horse serum and in a micro-aerophilic environment. Culture isolation of *T. equi* is more sensitive than for *B. caballi*. Giemsa-stained blood smears are prepared from cultures daily for 7 days (Avarzed *et al*., 1997; Ikadai *et al*., 2001). *Babesia caballi* is characterised by paired merozoites connected at one end. *Theileria equi* is characterised by a tetrad formation of merozoites or 'Maltese cross'. Confirmation of the diagnosis is by PCR (see Chapter 3.6.8 *Equine piroplasmosis*).

Molecular diagnosis is recommended for the testing of biological products that do not contain whole blood or organs. Molecular diagnosis by PCR or loop-mediated isothermal amplification (LAMP) assay are the most sensitive and specific testing methods for detection of the pathogens of equine *piroplasmosis* (Alhassan *et al*., 2007).

5. Detection of viruses in biological materials

In brief, general testing usually includes the use of continuous and primary cell lines of the source species, e.g.; cells of known susceptibility to the likely viral contaminants, which are inoculated for a period of up to 4 weeks with weekly subcultures. Virus seeds also require testing on a primary cell line of the species in which the final product is intended. At Day 21 or 28, assessment of the monolayers is done using H&E staining to assess CPE, and haemadsorption with guinea-pig and chicken RBC to assess the presence of haemadsorbing agents. Note that general testing is useful as a screening tool though not sufficiently sensitive enough to detect all viruses of concern.

Specific testing requires test material to be inoculated on to sensitive, susceptible cells lines for the virus to be excluded; the amplification process in cell culture is usually up to 28 days but depending on the virus, may require longer culturing times. Detection of specific viral contaminants is by recognition of CPE in conjunction with more sensitive antigen detection or molecular tests such as FAT and PCR and ELISA after the amplification process in cell culture.

All testing using cell lines to amplify for target viruses is contingent on the sensitivity of the cells for the target agent and the ability to recognise the presence of the agent in the cells. The quality, characteristics, and virus permissibility profile of cell lines in use should be determined as fit for purpose and appropriately maintained. Positive and negative controls should be used at all passages of cell culture to determine sensitivity and specificity. Interference testing should be performed at first pass to ensure that the test sample does not inhibit the growth of the virus being excluded for.

5.1. An example of general testing for the exclusion of viruses from virus and cell seed stocks used in production of veterinary vaccines

If the test virus inoculum is cytopathogenic, the effect must be specifically neutralised without affecting the likelihood of isolation of the target agent. For affected cell type, 1 ml of the test master (or working) virus seed (MVS) is thawed or reconstituted and neutralised with the addition of 1 ml mono-specific antiserum. The serum must be shown to be free from antibodies against any agents for which the test is intended to detect. Antiserum must be tested for nonspecific inhibiting affects. Serum should be of sufficiently high titre to neutralise the seed virus effectively with the use of an approximately equal volume or less of serum. A microplate titration is used to determine the titre of the antiserum required to neutralise the MVS of concern. The antiserum is allowed to neutralise the MVS at 37°C for 1 hour. The MVS and antiserum mixture is then inoculated on to a 75 cm^2 flask with appropriate cells. If the MVS is known to be high-titred or difficult to neutralise, the blocking antiserum can be added to the growth medium at a final concentration of 1–2%.

Master cell stocks do not require a neutralisation process.

The cells should be passaged weekly up to a 28-day period. Certain relevant viruses may be selected as indicators for sensitivity and interference (positive controls) but these will not provide validation for the broader range of agents targeted in general testing. The final culture is examined for cytopathology and haemadsorption.

May–Grünwald–Giemsa or H&E staining procedures are used to assess for cytopathological changes associated with virus growth. Monolayers must have a surface area of at least 6 cm^2 and can be prepared on chambered tissue culture slides and incubated for 7 days. The plastic wells of the slides are removed leaving the rubber gasket attached to the slide. The slides are rinsed in Dulbecco's phosphate buffered saline (PBS), fixed in acetone, methanol or formalin depending on the stain used and placed on a staining rack. For May–Grünwald–Giemsa staining: the slides are stained for 15 minutes at room temperature with May–Grünwald stain diluted 1/5 with absolute methanol. The May–Grünwald stain is removed by inverting the slides. The slides are then stained for 20 minutes with Giemsa stain diluted 1/15 in deionised water. The Giemsa stain is removed by inverting the slides and rinsing them in deionised water for 10–20 seconds. The slides are air-dried and mounted with a coverslip using paraffin oil. The May–Grünwald–Giemsa stain differentially stains ribonucleoprotein (RNP); DNA RNP stains red-purple, while RNA RNP

stains blue. The monolayers are examined with a conventional microscope for the presence of inclusion bodies, an abnormal number of giant cells, or other cytopathology attributable to a viral contaminant of the test product. The inoculated monolayers are compared with suitable control non-inoculated monolayers. If specific cytopathology attributable to an extraneous virus is found, results are reported, and additional specific testing may be conducted.

Testing for haemadsorption uses 75 cm^2 area monolayers established in tissue culture flasks after the 28-day passage period described above. Guinea-pig, chicken, and any other blood for use in this assay is collected in an equal volume of Alsever's solution and may be stored at 4°C for up to 7 days. Immediately prior to use, the stored erythrocytes are again washed by adding 5 ml of blood in Alsever's solution to 45 ml of calcium and magnesium-free PBS (PBSA) and centrifuging in a 50 ml centrifuge tube at 500 ***g*** for 10 minutes. The supernatant is aspirated, and the erythrocytes are suspended in PBSA and re-centrifuged. This washing procedure is repeated at least twice until the supernatant is clear. Erythrocytes from each species are combined by adding 0.1 ml of each type of packed blood cells to 100 ml of PBSA. The erythrocytes from different species may be kept separate or combined, as desired. To each flask, add 5 ml of the erythrocyte suspension, and incubate the flasks at 4°C for 30 minutes. The monolayers are washed twice with PBSA and examined for haemadsorption. If no haemadsorption is apparent, 5 ml of the erythrocyte suspension is added to each flask; the flasks are incubated at 20–25°C (room temperature) for 30 minutes, rinsed as before, and examined for haemadsorption. Separate flasks may be used for each incubation temperature if desired. Monolayers are examined for the presence of haemadsorption using an illuminated light box and microscopically. Non-inoculated monolayers are used as negative controls. The PBSA and fresh erythrocytes should prevent most nonspecific haemadsorption from occurring. If specific haemadsorption attributable to an extraneous agent is found, results are reported, and additional specific testing may be conducted.

Specific testing requires specialised test procedures that are sensitive to amplifying a particular agent in culture and then detection of that agent by means of fluorescence, antigen-capture ELISA or PCR; whichever is more sensitive. Specific testing is usually required when general procedures are not adequate for effective exclusion of more fastidious, viruses Some examples are listed in Table 1.

5.2. An example of specific virus exclusion testing of biologicals used in the production of veterinary vaccines

5.2.1. Porcine epidemic diarrhoea virus (PEDV)

Trypsin is required at inoculation and in the culture medium for isolation of porcine epidemic diarrhoea virus (PEDV) in Vero cells (CCL81, ATCC). Just confluent monolayers (100%) are required; under confluent monolayers are more sensitive to the presence of trypsin and will be destroyed well before the 7 days required for each passage in culture. An over confluent or aging monolayer will not be sensitive for growth of PEDV. Maintenance media (MM) formulation consists of Earle's MEM (minimal essential medium) (with 5.6 M HEPES [N-2-hydroxyethylpiperazine, N-2-ethanesulphonic acid] and glutamine) + 0.3% Tryptose phosphate broth, 0.02% yeast extract and 4 μg/ml TPCK treated trypsin. The addition of the trypsin into the MM should occur on the day the media is to be used.

Prior to inoculation, confluent 75 cm^2 monolayers are washed twice with the MM (with trypsin added) to remove FCS. Virus or cell seed (1 ml) is added with 1 ml of MM to each monolayer; incubate at 37°C for 2 hours, then add 30 ml/flask of MM. Negative control monolayers of the same size are set up prior to inoculation of test material. Positive and interference controls are set up last in a separate laboratory area. Assessment for sensitivity and interfering substances requires assessment of PEDV of known titre. A control for interference using co-inoculation of test sample and PEDV needs only to be set up on the first pass. Positive controls must be set up at every pass to ensure each monolayer used gives expected sensitivity. PEDV virus is titrated in log dilutions starting at 10^{-1} to 10^{-6} in MM (depending on the endpoint titre of reference virus) in duplicate rows of 6 wells of a 24-well tissue culture plate. For the interference test, PEDV is titrated in the same dilution series but using MM spiked with a 10% volume of test material. Decant off the growth media and discard. Wash plates to ensure no FCS is present. Two washes using approximately 400 μl/well MM (with trypsin added) are sufficient.

Add 100 µl of diluted virus on to each of two duplicate wells. Rock inoculated plates to distribute the inoculum evenly over the surface of the monolayer. Incubate at 37°C with 5% CO_2 for 2 hours then add 1 ml volumes/well of MM.

After 7 days, 75 cm^2 monolayers have cells disrupted using two freeze–thaw cycles at –80°C. Positive control plates are read for end-point titres, and these are compared with virus in the presence of test material to ensure titres are comparable and interference has not occurred. Freeze–thaw lysates are clarified at 2000 ***g*** for 5 minutes and re-passed on to newly formed monolayers as for the first passage. Passages are repeated until a total of four passages are completed at which point cell lysates are assessed by PCR for detection of PEDV and day 7 monolayers in 24-well plates are fixed and stained by IFA. If seed virus is to be tested and requires neutralisation using antiserum, extra care in the isolation of PEDV needs to be considered. Trypsin is rendered inactive in the presence of serum proteins and without trypsin present, PEDV is unable to grow in cell culture. Washing off the inoculum with two MM washes is required after an extended adsorption time of up to 4 hours to ensure acceptable sensitivity.

J. INFORMATION TO BE SUBMITTED WHEN APPLYING FOR AN IMPORT LICENCE

When undertaking risk analysis for biologicals, Veterinary Authorities should follow the *Terrestrial Manual*. The manufacturer or the Veterinary Authority of the exporting country should make available detailed information, in confidence as necessary, on the source of the materials used in the manufacture of the product (e.g. substrates). They should make available details of the method of manufacture (and where appropriate inactivation) of the substrates and component materials, the quality assurance procedures for each step in the process, final product testing regimes, and the pharmacopoeia with which the product must conform in the country of origin. They should also make available challenge organisms, their biotypes and reference sera, and other means of appropriate product testing.

K. RISK ANALYSIS PROCESS

Risk analysis should be as objective and transparent as possible and should be performed in accordance with Section 2 of the *Terrestrial Code*, and certification in line with Section 5 of the *Terrestrial Code*. Of necessity, assessment of the country and commodity factors and risk reduction measures will be based largely on manufacturers' data. These data depend on quality assurance at all stages of manufacture, rather than on testing of the final product alone.

Domestic exposure may be influenced by the approved usage of the product. Veterinary Authorities may place limits on usage of some products (e.g. restricting usage to institutions of appropriate biosecurity).

L. BIOCONTAINMENT

Suitable biocontainment may be necessary for many forms of biologicals. In particular, the importation of exotic micro-organisms should be carried out in accordance with Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*.

CHAPTER 1.1.10.

VACCINE BANKS

SUMMARY

Vaccine banks provide antigen or vaccine reserves, either of ready-to-use vaccines or of antigenic components that can be quickly formulated into the final product for emergency use or other vaccination campaigns. They may be established for national or international use. For some international banks in particular, it is important to define the drawing rights of the members of the controlling consortium, and to establish clear governance mechanisms. For banks managed by intergovernmental organisations such as WOAH, appropriate financing should be in place, together with eligibility criteria for access to the bank. Vaccine banks may be deployed by Veterinary Authorities for different purposes ranging from systematic mass vaccinations, to emergency vaccinations, or to strategic interventions.

The major advantage of storing antigen in banks over storing formulated vaccines is the ability to store bulk vaccine antigen as concentrated stocks with prolonged retention of potency in low temperature storage. Appropriate serotypes and strains, alone or in combination, can also be selected from the bank according to the needs at the time of deployment. The disadvantage of antigen banks is the delay between the decision to deploy and the availability of the final formulated vaccine. This delay can, to some extent, be reduced by pre-testing trial batches of vaccine as part of acceptance into the bank, provided that agreement has been reached with the Competent Authority to provide early release certification based on reduced testing in the event of need.

Ready-to-use formulated vaccines can be deployed rapidly and are available for immediate use for the full duration of the shelf life of the vaccine. When not used, a disadvantage is the defined shelf life as this is usually much shorter than for banked antigens stored at low temperature. Also, for pathogenic agents that have several serotypes and/or show extensive strain variation in their antigenic characteristics, the fixed formulation may not sufficiently protect against infection with the strain involved in a given outbreak.

Whether storing antigen or ready-to-use formulated vaccines, plans should be in place to replenish stocks before the end of the shelf life or, where possible, to rotate and replace stock in a timely manner. Vaccines and antigens beyond their approved shelf life are not acceptable for use and must be discarded and destroyed.

Planning for the components of a vaccine bank, and for the quantity of material to be stored, should involve all relevant stakeholders including the Competent Authorities, vaccine bank administrators, vaccine manufacturers and reference laboratories. When combined with recommendations from reference laboratories on matching of field and vaccine strains, information technology (IT) tools involving modelling and epidemiological risk assessment can help in deciding the amounts and strains to include in a bank. Relevant information to inform the planning should include the epidemiology of the disease in question, its geographical occurrence, the nature of the pathogen, patterns of animal production, movement and trade, pre-existing vaccine coverage of the population and the logistics of deployment of the banked vaccine.

The regulatory principles of vaccine production apply equally to vaccine banks and vaccines produced should comply with the requirements of Chapter 1.1.8 Principles of veterinary vaccine production *of this* Terrestrial Manual *and the disease-specific WOAH standards in Part 3 of this* Terrestrial Manual.

A. DEFINITION OF A VACCINE BANK

Vaccine banks are defined as strategic antigen or vaccine reserves. Banks may consist of physical stocks of antigen or vaccine stored in a made-for-purpose facility or may be based on contractual arrangements with manufacturers to supply agreed amounts of one or more defined vaccines within a specific period of time. Hybrid approaches are also possible. Banks may hold the antigen component, or a ready-to-use formulated vaccine, or both. The vaccines may be deployed for different purposes ranging from systematic mass vaccination to emergency vaccinations, or to strategic interventions.

B. TYPES OF BANKS

Vaccine banks can be classified by their geographical coverage as well as by the nature of product stored.

A country may hold its own national bank, or it may be part of a larger group of countries that share a bank, which either have predefined drawing rights, or an *ad hoc* mechanism to determine these drawing rights. Such international consortia are based on shared risk and may share a common geographical region, or have similar disease status and approach to preventing and controlling a given disease. The bank may be held on the territory of one or several of the group members or be retained by the manufacturer(s). Intergovernmental organisations have also recognised the need to set up banks to support and prioritise immediate access to high quality vaccines, in particular by low- to middle-income countries, and thereby avoid the delay associated with conventional procurement procedures. An adequate system of governance should be established for all vaccine banks.

Certain vaccine antigens can be stored as concentrated stocks and retain potency for several years at temperatures below –70°C, depending on the stability of the antigen. Such antigens have to be formulated into vaccines before deployment. Using this approach, the vaccine composition, including choice of strains and potency, can be adjusted according to need, provided that such flexibility has been built into the approval process of the vaccine concerned (usually termed multi-strain vaccine approval). Formulation of antigens for use may be done either by the manufacturer of the antigen or in a dedicated facility maintained by the bank members. In the latter case, the facility needs an appropriate license to formulate the final product in compliance with the principles of Good Manufacturing Practice (GMP) or other manufacturing standards that apply in the country concerned. In these situations, the antigen bank itself assumes the responsibilities of the holder of the product licence for the vaccine released (also termed marketing authorisation or product registration). Vaccine manufacture and release need to be approved by the national regulatory authority where the vaccine is produced. If used in a different country, import and use of the vaccine need to be approved by the country in which it is deployed. Depending on the country concerned, licensing authorities may require that vaccines released from vaccine banks meet the same standards as the commercial vaccines used in food-producing animals or may apply less demanding standards, in particular where vaccinated animals are not intended to enter the food chain (i.e. vaccination and subsequent stamping out). Approval from the national Competent Authority will also cover aspects such as product labelling and literature, such as the product leaflet, in line with the approved conditions for use as detailed in a Summary of Product Characteristics (SPC), or equivalent documents.

In addition to ensuring appropriate approvals for manufacture, formulation and storage, the arrangements for vaccine banks need to clearly define all the essential requirements including: time between receiving an order and delivery, import permits, customs clearance, transportation, and maintenance of the cold chain. In the case of an antigen bank, specific arrangements are recommended to ensure that the contract for the supply of the antigen(s) includes a requirement for the associated supply of control samples (see Sections D. *Quantities of vaccine required in a bank* and F. *Acquisition of antigens or vaccines for a bank*). Contractual arrangements with manufacturers should include storage, formulation, availability of reagents and suitably sized vials, and the supply of formulated vaccines.

The main advantages of vaccine banks holding antigens are the speed that antigens can be turned into the final licensed vaccine when compared with vaccine production beginning from the working seed, the long shelf life of the antigen, and the option for a flexible combination of antigens to address different vaccination strategies. However, there is always a necessary time delay between giving the order for formulation and the availability of the ready-to-use formulated vaccine, which may not be suitable for rapid vaccination in emergency situations. Where appropriate approvals have been received from the Competent Authority responsible for batch release, frequently referred to as early release certification, this delay can be reduced. Early release is possible in an emergency situation (for example an outbreak of foot and mouth disease [FMD] in a country previously free of that disease as

foreseen in Chapter 3.1.8. *Foot and mouth disease* [*infection with foot and mouth disease virus*]), in a quality controlled manufacturing system in accordance with WOAH standards (WOAH *Terrestrial Manual* Chapter 1.1.8 *Principles of veterinary vaccine production*). Reduced testing might be acceptable at the time of release provided that full finished product testing has previously been performed on a batch of vaccine that is representative of the product to be released, particularly in terms of the method of production and the type and amount of antigen.

Ready-to-use formulated vaccines can be deployed rapidly and have a pre-determined formulation with a finite shelf life that is indicated in the product registration and has been validated by appropriate testing. The approved shelf life will depend on the characteristics of the vaccines when stored in appropriate temperature-controlled facilities as described in the product literature.

The main advantage of ready-to-use formulated vaccines is their immediate availability for use, though this should be balanced with what remains of the ready-to-use formulated vaccines' approved shelf-life when accessed, as it could lead to a very restrictive period of application compared with vaccines formulated on request from banked antigen stocks. Another inconvenience of ready-to-use formulated vaccines for pathogenic agents that have several serotypes and/or exhibit extensive strain variation in their antigenic characteristics is that the fixed formulation may not sufficiently protect against the strain involved in a given outbreak.

For all banks, whether storing antigen or ready-to-use formulated vaccines, there is the need to renew the stocks at the end of the approved shelf life of the antigen or formulated vaccine, respectively. Antigens or formulated vaccines that are beyond their approved shelf life should not be used and must be discarded and destroyed in appropriate specialised facilities (Lombard & Füssel, 2007) unless suitable studies have been carried out and regulatory approval obtained for extending the shelf life. Renewal orders and managing the period between the expiry date of the current stock and the arrival of new stock should be considered in a timely manner. Alternatively, stocks of antigen or ready-to-use formulated vaccines could be rotated and replenished to ensure there is a continuous supply of product within shelf life. Rotation of stock is relatively easily achieved by manufacturers where a market exists for the vaccine concerned. Rotation requires more forethought in the case of banks intended for emergency use, but some banks make antigen or vaccine available to non-member countries in cases of emergency or to low- to middle-income countries in a timely manner to assure its use before the scheduled expiry date.

Authorities responsible for disease control may set up contractual arrangements for long-term supply with one or more manufacturers rather than setting up physical vaccine banks. This approach avoids the substantial capital costs of setting up and maintaining the complex facilities that are needed for storage and production of vaccine. Furthermore, the responsibility for gaining and maintaining regulatory approvals rests with the manufacturer rather than the vaccine bank holder. The costs of maintaining facilities, and of carrying out the trials necessary to demonstrate quality, safety and efficacy in line with at least the minimum standards defined in the WOAH *Terrestrial Manual* have increased substantially as requirements have developed over the years. Commercial manufacturers have the necessary facilities and operate to these standards routinely whilst it can be challenging for non-commercial vaccine manufacturers to meet the required standards. This is particularly the case when countries require full regulatory approval before permitting use of the vaccine in animals of food-producing species, even under exceptional circumstances. In such long-term arrangements, a contract is concluded whereby manufacturers agree to supply defined amounts of one or more vaccines that meet agreed technical specifications within a specified time period of receiving an order. In this way the risks and benefits are shared between the contractor and the manufacturer. Contractors benefit by assuring the availability of an appropriate vaccine in the event of need and manufacturers benefit from a predictable source of funding to maintain their facilities, licenses and stocks even when vaccines are not used to control an outbreak.

C. SELECTION OF VACCINES FOR A BANK

Depending on the disease targeted and the likely contingency requirements, a range of vaccine strains may be required. Competent Authorities in consultation with the vaccine bank administrators and relevant reference laboratories must decide which vaccine strains should be held and whether they should be stored as a separate antigen component for subsequent formulation, or as a ready-to-use formulated vaccine. The value of any vaccine bank is dependent upon the appropriateness of what it holds for field application, particularly in respect of pathogenic agents that have several serotypes and/or exhibit extensive strain variation in their antigenic characteristics.

The potential for an outbreak not adequately covered by a banked vaccine must be alleviated by continual monitoring of the global disease situation, taking into account animal health information systems such as WOAH's WAHIS[1] and disease-specific updates in the periodic reports by international reference laboratory networks, and supported by laboratory genetic and antigenic characterisation facilitated by reference and other suitable laboratories. Additional vaccine strains may need to be included in the banks' portfolio or, where no suitable vaccine strain is available, developed as quickly as possible for subsequent inclusion in the bank. Close cooperation is therefore required between reference laboratories, manufacturers, international animal health organisations and bank managers to ensure that newly emerging strains are rapidly identified and made available to manufacturers for evaluation as potential new vaccine seed strains.

The world is an interdependent community that encompasses rapid and extensive movement of people, animals and animal products, and the increasing awareness of deliberate release of a pathogen through bioterrorism, heightens the risk of disease incursion and makes prediction of a specific threat difficult. Increased cooperation and collaboration between different international, regional and national reference laboratories, vaccine banks, and national, regional, international authorities or organisations should be encouraged as well as mechanisms for consultation with vaccine manufacturers. Structured risk assessment, preferably conducted at a country or regional level, should be used to determine the antigen or vaccine to be stored with a suitable priority level. In the case of FMD, a specific tool (Pragmatist) has been made available for this purpose. Effective risk management of FMD is only possible on the basis of knowledge of what strains are actively circulating and the extent of antigenic match between these strains and the virus antigens stored in the vaccine bank. This, in turn, relies on the continual submission of outbreak strains to reference laboratories for vaccine matching studies. Authorities are encouraged to share as much information as possible between themselves for the purpose of effective risk assessment and risk management whilst recognising that there may be a need to restrict the amount of information relating to the storage of antigens or vaccines that is made publicly available on the basis of both national security and, in some cases, commercial confidentiality.

D. QUANTITIES OF VACCINE REQUIRED IN A BANK

The decision as to how many doses of vaccine are required is complex, embracing questions of epidemiology, vaccinology, logistics and resources (human, technical and financial).

Factors bearing on the decision include:

i) the nature of the disease in question (serotypes, strains, pathogenesis, routes and rapidity of spread, presence and competence of vectors, etc.);

ii) the characteristics of the available vaccines (serotypes, strains, monovalent or polyvalent types of formulation), compatibility with DIVA strategies (DIVA: differentiation of infected from vaccinated animals), potency of the vaccines and the antigenic match between field and vaccine strains;

iii) the number, species, location and density of the animals to be protected;

iv) the types of emergency vaccination likely to be applied, and the number of doses in the vaccination regime;

v) logistical requirements (the availability of trained personnel, storage facilities, maintenance of the cold chain, transport, vaccination equipment, consumables, etc.);

vi) the current and predicted global, regional and national epidemiology of the disease;

vii) patterns of animal production, movement and trade;

viii) analysis of the risk of the introduction and spread of the disease in question (which may include epidemiological modelling);

ix) application of contingency planning (including risk–benefit and cost–benefit analysis and the construction of decision trees, awareness and acceptance by stakeholders).

Decisions on the quantity of the product inevitably involve a compromise between the potential economic impact of the disease, fixed cost of the maintenance of the vaccine bank, cost of purchase, storage and replacement, cold

1 https://wahis.woah.org/#/home

chain capacities of the beneficiaries and the likely number of doses required. The post-vaccination disease control and surveillance strategy further impacts the decision on the number of vaccine doses required.

The minimum vaccine requirement should be based on a country's planned vaccination strategy as detailed in its contingency plan. In the case of FMD, a modelling tool (VADEMOS) has been developed to estimate current and future vaccine dose demand at national, regional and global levels. The procurement of additional supplies of vaccine, either from other banks or from commercial sources, is likely to take considerable time. It would be beneficial in terms of cost, time and volume, for different national or regional vaccine banks to cooperate, or to consider setting up regional or international vaccine banks.

When relevant, vaccine banks may adopt a balanced approach combining a proportion of stored antigens (core strains and optional strains), with a proportion of ready-to-use formulated vaccines (for rapid deliveries).

E. REGULATORY CONSIDERATIONS

The manufacture of a vaccine, including vaccines intended to be exported for inclusion in a vaccine bank in a third country, requires approval by the national Competent Authority of the country in which the vaccine is produced, usually in the form of a manufacturing licence. Likewise, the deployment and use of a vaccine requires approval by the national Competent Authority of the country in which it is used. National Competent Authorities in WOAH Members should ensure that vaccines comply with at least the minimum standards defined in the relevant general chapters (e.g. chapter 1.1.8 and the relevant chapters in Section 2.3 *Veterinary vaccines*) and disease-specific chapters of this WOAH *Terrestrial Manual* (such as 3.1.8 *Foot and mouth disease).* National Competent Authorities may apply WOAH standards or may apply more stringent requirements as specified in national legislation. In addition to licensing products in compliance with full regulatory requirements in inter-epidemic periods, most countries also have systems in place to approve products more rapidly and with reduced data requirements in emergency situations or where there is no prospect of generating a full data package. In the event of disease emergencies, countries may also approve the use of unauthorised products or products authorised in another country, relying on existing data for the product concerned and placing specific controls on its import and use. In view of the different approaches adopted by different countries and for different diseases, those intending to use antigen and/or ready-to-use vaccines procured from a vaccine bank need to ensure that they are aware of the regulatory requirements for the production, regulatory approval, and use of vaccines produced from the bank and how these requirements will be met.

For vaccine banks the following additional considerations apply, with more detail developed throughout this chapter, as relevant:

i) storage conditions:
    a) facilities,
    b) containment of stored antigen or vaccine,
    c) labelling of stored antigen or vaccine;
ii) monitoring of stored concentrated antigen;
iii) transport to storage facilities;
iv) transport for deployment:
    a) transport of antigen for reformulation,
    b) transport of vaccines for use.

In setting up and gaining regulatory approval for manufacture, the vaccine bank will need to demonstrate that these aspects are conducted in line with the relevant chapter in the WOAH *Terrestrial Manual* and with national requirements.

Countries requesting vaccines from a vaccine bank need to ensure that their contingency plans include arrangements for import permits, customs clearance and maintenance of the cold chain as required.

F. ACQUISITION OF ANTIGENS OR VACCINES FOR A BANK

According to the type of bank and the disease concerned, the acquisition of the appropriate vaccine(s) or antigen(s) will depend on whether they are available from the commercial sector, government institutions or other production facilities. Irrespective of the source, antigens and vaccines need to be produced in facilities approved in line with regulatory requirements for manufacture and need to meet the quality requirement specified in the relevant regulatory approval.

Vaccine banks may use direct procurement or may use international calls for tender to acquire antigens or vaccines. They may wish to seek advice from appropriate official regulatory authorities to ensure that the standards specified in the technical specifications for the procurement are fully aligned with the terms of regulatory approval. Requests for tenders can then ensure not only a competitive price, but also a veterinary medicinal product manufactured to an acceptable level of quality, the standards being at least those set out in this WOAH *Terrestrial Manual*. For diseases where there is official WOAH recognition of that disease status, vaccines used in the Members concerned must comply with the standards in the WOAH *Terrestrial Manual*. It is recommended that the process of selecting suppliers should not focus solely on lowest cost but should also take into consideration technical and quality criteria as well as delivery capacities. This could be achieved by a stepwise process, first assessing the technical proposal responding to the technical specifications, followed by an evaluation of the commercial bid of the eligible candidate suppliers. The technical specification should establish that suppliers can produce the desired vaccines or antigens in the necessary amounts within a specified time period that includes the time required for mandatory tests of compliance such as sterility, safety, and potency.

G. STORAGE OF VACCINES OR ANTIGENS IN A BANK

It is important that the areas of storage for vaccine banks comply with recognised quality standards (e.g. chapter 1.1.8), which also address security of the premises (e.g. restricted access to premises, logbooks, continuity of access to electric power). Storage areas for vaccine banks should be regularly inspected by the Competent Authorities to ensure continual compliance. In the case of a vaccine that has regulatory approval, the storage conditions for both the antigen and for the formulated vaccine that is stored before release form part of the approval. Likewise, the location and operation of storage areas fall within the scope of the certificate of GMP (or other manufacturing standard) approved by the national Competent Authority. Any deviation from the approved conditions or areas for storage therefore requires approval from the relevant regulatory authority. If antigens are stored in one location but formulated and finished in another, both areas need to be covered by the 'GMP envelope' and agreed arrangements must be in place for transfer of material between the two.

If the vaccine bank is co-located with a laboratory or other facility where pathogens are handled, the bank storage facilities should be completely independent and be protected by positive air pressure with high efficiency particulate air (HEPA) filtration at the air inlets. Maintenance and monitoring personnel should, where they have had a possible exposure to relevant infection, obey a quarantine procedure before entering the bank.

Storage of antigens or vaccines in a bank should be appropriate to the product. The antigen may be a chemically inactivated or killed organism, a subunit derived from recombinant technology, or it may be a live vaccine based on an attenuated or recombinant strain. Antigens may be concentrated in frozen liquid form held at temperatures below –70°C in suitable containers that are appropriately labelled (see e.g. Chapter 3.1.8, Section C.6 *Storage and monitoring of concentrated antigens*). Freeze-dried vaccines and their diluents should be stored in accordance with the manufacturer's specification, typically at +4°C or –20°C, or as appropriate. Backup storage, equipment and contingency power supplies should be in place. For all methods of storage it is vitally important that vaccines or antigens are optimally maintained and routinely monitored, and that their storage is properly documented, in order to have assurance that they will be fit for use when needed. Managers of vaccine banks should therefore ensure that the necessary arrangements are in place to monitor their reserves on a routine basis as specified in the product licence and to include, where necessary and at appropriate time intervals, a testing regime to ensure integrity of the antigen component or acceptable potency of the final product. For example, storage facilities should be equipped with continuous temperature recording and alarm systems to detect divergence outside the required range; periodic inspection should also be carried out of the antigen containers for cracks or leakage. In this context, managers may wish to also consider the possibility of independent testing, or of greater reliance on overseeing or auditing of the manufacturer's test procedures.

In the case of antigen-containing banks, there is a need for routine stability testing of stocks. Sufficient smaller volume samples that are representative of the bulk antigen stock are necessary for such purposes and both bulk and samples should be stored side by side.

Where the requirement is to hold antigens or vaccines at a site other than at the principal site of manufacture, Competent Authorities should ensure that appropriate testing is carried out before the antigens are formulated into finished vaccine. Any new antigens should be held in a defined quarantine area until the necessary tests have been performed to formally accept them into the bank.

H. DEPLOYMENT PLANNING

Deployment planning addresses all aspects of the release of antigen for formulation into the final product, and the release and delivery of the ready-to-use formulated vaccine to the destination.

The request to deploy should be made by the Competent Authority(ies) of the requesting country or region, the decision for deployment being taken in agreement with the governance and management of the vaccine bank. The approval issued by the Competent Authority will include the conditions that must be met for release of the vaccine from the control of the manufacturer into the distribution chain. This can take a number of forms, from a simple import license for specific batches of vaccine through to official control authority batch release, depending on the terms of the license and the countries in which the vaccine is to be released and used. Early release may be possible if approved for emergency situations or release may only be possible once all tests are completed and verified. Members of vaccine banks need to ensure that the arrangements for batch release are fully understood and agreed with their respective Competent Authority to avoid delay in the event of need.

For the optimal use of a vaccine bank, the order for deployment should be informed, where appropriate, by results from a diagnostic laboratory (preferably a reference laboratory) with the ability to characterise the agent causing the disease and match the field strain with the available stored antigens or the ready-to-use formulated vaccines. In recent years a greater focus has been placed on the fate of vaccinated animals and the implications of vaccination as set out in the *Terrestrial Code* Chapter 4.18 *Vaccination*. For many diseases, DIVA vaccines have been developed together with companion diagnostic tests to substantiate that vaccinated animals and their products are free from infection. Successful deployment of DIVA vaccines requires the use of an accompanying diagnostic test. An important aspect of licensing vaccines with DIVA claims is to verify that the claims made for the combination of the vaccine and the accompanying test have been verified by the manufacturer to an acceptable standard and in line with general and specific guidance in the WOAH *Terrestrial Manual* (e.g. Chapter 3.1.8. Section C.5.4 *Purity: testing for antibody against NSP* for FMD vaccines). Using vaccines and accompanying tests that have been independently verified as complying with WOAH standards is very helpful to countries.

Competent Authorities should have emergency plans to ensure that the stored vaccine is distributed and administered to meet disease control goals. In an outbreak situation, the speed of the implementation of the vaccination programme is critical in reducing the number of infected premises, the duration of the epidemic and, for certain diseases, the number of animals that need to be culled. The Competent Authorities should ensure that the necessary cold-chain facilities for vaccines and diluents, if appropriate, are available, that vaccination protocols are defined in advance, that vaccination teams are established and trained appropriately, that all the other necessary documentation, equipment, reagents and clothing are stored at sufficient levels to support any potential vaccination campaign, and that stakeholders are aware of the need for such a campaign (see WOAH *Terrestrial Code* Chapter 3.5. *Communication*). Performing periodic exercises and simulations should be considered.

I. CONSIDERATIONS FOR VACCINE BANKS MANAGED BY INTERGOVERNMENTAL ORGANISATIONS

Vaccine banks managed by intergovernmental organisations, such as WOAH, may rely on specific funds for financing, to achieve prevention and control of specific diseases. Such mechanisms have been used to establish vaccine banks for FMD, peste des petits ruminants, avian influenza, and rabies for dog vaccination, and may be considered for other animal diseases in the future.

With the financial support of donors, in the context of international aid or with the use of other financial mechanisms such as trust funds or complementary funding, an intergovernmental organisation (regional or global) may manage

regional or global vaccine banks that are licensed and retained by the manufacturers selected through specific international calls for tender. Multiple donor funding mechanisms allow for cost sharing (establishment or replenishment), and for the management of donor-specific requirements.

Eligibility criteria are defined for countries that have access to such vaccine banks as well as guidelines on the use of regional and global vaccine banks. Depending on the disease, these banks may include vaccines produced and delivered on demand (planned deliveries), or specific replenishment mechanisms for rolling stocks.

The benefits of regional (or global) vaccine banks are numerous and seek to:

i) save costs (economies of scale);

ii) facilitate the delivery of determined quantities of high quality vaccines complying with WOAH standards;

iii) deliver more doses at a lower cost with access to more vaccine strains;

iv) reduce the risks associated with the storage of vaccines;

v) facilitate the harmonised implementation of regional or global disease control strategies;

vi) create incentives for the implementation of disease control programmes;

vii) reduce the number of procurement procedures;

viii) promote the use of vaccines that comply with WOAH quality standards for national and international disease control programmes.

Specific financial mechanisms can also allow countries or intergovernmental organisations to purchase directly from such banks.

Collaboration between vaccine banks (including those managed by intergovernmental organisations) and regional organisations is an economical way of increasing the amount of emergency vaccines available. Care is required to ensure that collaborating vaccine banks and regional organisations operate to the same or equivalent standards. Drawing rights should be clearly defined, and regular contact should be maintained between vaccine banks and regional organisations to confirm the quality of the vaccines. In the case of shared banks, regulatory compliance needs to be addressed at an early stage to ensure that vaccine produced from the bank is manufactured to WOAH quality standards and will therefore be readily accepted for use in recipient countries.

Some vaccine banks also rely on long-term supply arrangements with selected providers that may include replenishment mechanisms, production on demand for non-urgent or planned deliveries, and buy-back schemes. While vaccine banks often hold physical stocks of antigens or vaccines, it is also possible to establish virtual vaccine banks with reduced physical stock. Specific service contracts between the bank holder and the manufacturers operating any of the above solutions should set out clear obligations, pricing specifications, maximum delays for delivery and contractual penalties in case of failure to meet the conditions of the service contract.

SECTION 2.1.

LABORATORY DIAGNOSTICS

CHAPTER 2.1.1.

LABORATORY METHODOLOGIES FOR BACTERIAL ANTIMICROBIAL SUSCEPTIBILITY TESTING

SUMMARY

With the increase in bacterial resistance to traditionally used antimicrobials, it has become more difficult for clinicians to empirically select an appropriate antimicrobial agent. As a result, in-vitro *antimicrobial susceptibility testing* (*AST*) *of the relevant bacterial pathogens, from properly collected specimens, should be performed using validated methods. Thus, AST is an important component of prudent antimicrobial use guidelines in animal husbandry worldwide and veterinarians in all countries should have these data available for informed decision-making.*

Although a variety of methods exist, the goals of in-vitro *antimicrobial susceptibility testing are either to provide a reliable predictor of how an organism is likely to respond to antimicrobial therapy in the infected host or to assess for surveillance purposes whether there has been development of resistance. This type of information aids the clinician in selecting the appropriate antimicrobial agent, aids in developing antimicrobial use policy, and provides data for epidemiological surveillance. Such epidemiological surveillance data provide a base to choose the appropriate empirical treatment* (*first-line therapy*) *and to detect the emergence and/or the dissemination of resistant bacterial strains or resistance determinants in different bacterial species. The selection of a particular AST method is based on many factors such as validation data, practicality, flexibility, automation, cost, reproducibility, accuracy, standardisation and harmonisation.*

The use of genotypic approaches for detection of antimicrobial resistance genes has also been promoted as a way to increase the speed and accuracy of susceptibility testing. Numerous DNA-based assays are being developed to detect bacterial antimicrobial resistance at the genetic level. These methods, when used in conjunction with phenotypic analysis, offer the promise of increased sensitivity, specificity, and speed in the detection of specific known resistance genes and can be used in tandem with traditional laboratory AST methods.

INTRODUCTION

The spread of multiple antimicrobial-resistant pathogenic bacteria has been recognised by the World Organisation for Animal Health (WOAH, founded as OIE), the Food and Agriculture Organization (FAO) and the World Health Organization (WHO) as a serious global human and animal health problem. The development of bacterial antimicrobial resistance is neither an unexpected nor a new phenomenon. It is, however, of increasing concern due to the frequency with which new emerging resistance phenotypes are occurring among many bacterial pathogens and commensal organisms, such as resistance to carbapenems, colistin, linezolid, macrolids, etc.

Historically, many infections could be treated successfully according to the clinician's past clinical experience or because susceptibility could be reliably predicted (i.e. empirical therapy); however, this is becoming more the exception than the rule (Walker, 2007). Resistance has been observed to essentially all of the antimicrobial agents currently approved for use in human and veterinary clinical medicine. This, combined with the variety of

antimicrobial agents currently available, makes the selection of an appropriate agent an increasingly challenging task. This situation has made clinicians more dependent on data from *in-vitro* antimicrobial susceptibility testing, and highlights the importance of the diagnostic laboratory in clinical practice.

A number of antimicrobial susceptibility testing (AST) methods are available to determine bacterial susceptibility to antimicrobials. The selection of a method is based on many factors such as practicality, flexibility, automation, cost, reproducibility, accuracy, accessibility and individual preference. Standardisation and harmonisation of AST methodologies, used in epidemiological surveillance of antimicrobial drug resistance, are critical if data are to be compared among national or international surveillance/monitoring programmes of WOAH Members. It is essential that AST methods provide reproducible results in day-to-day routine laboratory use and that the data be comparable with those results obtained by an acknowledged 'gold standard' reference method. Currently the reference AST method is the broth micro-dilution method that determines minimum inhibitory concentration (MIC) as described by the ISO (International Organization for Standardization, 2006). In the absence of standardised methods or reference procedures, susceptibility results from different laboratories cannot be reliably compared. The method used to select samples for inclusion in antimicrobial resistance surveillance programmes, as well as the methods used for primary bacterial isolation, are also important factors that should be standardised or harmonised to allow direct comparison of data between different regions; consideration of these issues is addressed in a WOAH document (Dehaumont, 2004).

As the science of AST has progressed, a greater understanding of the multiple factors that could affect the overall outcome of susceptibility testing has become clearer (WHO, 2017). This document provides guidelines and standardisation for AST methodologies, and interpretation of antimicrobial susceptibility test results.

1. Test requirements

The following requirements should be applied to achieve standardisation of AST methods and comparability of AST results:

i) the use of standardised AST methods is essential, including the harmonisation of AST test parameters such as media, inoculum, incubation time, quality controls, choice of antimicrobial agents and subsequent interpretive criteria,

ii) standardised AST methods, including all critical specifications and interpretive criteria, should be clearly defined, documented in detail and used by all participating laboratories,

iii) all AST methods should generate accurate and reproducible data,

iv) quantitative susceptibility data (MIC) should be reported,

v) establishment of national or regional reference laboratories is essential for the coordination of AST methodologies, interpretations and appropriate operational techniques used to ensure accuracy and reproducibility (e.g. quality controls),

vi) microbiological laboratories should implement and maintain a formal quality management programme (see Chapter 1.1.5 *Quality management in veterinary testing laboratories*),

vii) laboratories should have acquired a third party accreditation that includes the AST methodologies to be used within the scope of that accreditation. The accreditation body should meet accepted international Laboratory Accreditation Cooperation [ILAC]) standards and guidelines regarding the standards used for the accreditation process. The accreditation standards used should include the requirement for participation in proficiency testing programmes,

viii) specific bacterial reference/quality control strains are essential for determining intra- and inter-laboratory quality control, quality assurance and proficiency testing.

2. Selection of antimicrobials for testing and reporting

Selecting the appropriate antimicrobials for susceptibility testing can be difficult given the vast numbers of agents available. The following guidelines should be noted:

i) the FAO/WOAH/WHO expert workshop on non-human antimicrobial usage and antimicrobial resistance recommends creating a list of veterinary and human critically important antimicrobials for susceptibility testing and reporting,

ii) selection of the most appropriate antimicrobials is a decision best made by each WOAH Member in consultation with the appropriate bodies and organisations,

iii) antimicrobials in the same class may have similar *in-vitro* activities against select bacterial pathogens. In these cases, a representative antimicrobial should be selected that predicts susceptibility to other members of the same class,

iv) certain microorganisms can be intrinsically resistant to particular antimicrobial classes; therefore it is unnecessary and misleading to test certain agents for activity *in vitro.* The type of intrinsic resistance has to be determined for these organisms from either the scientific literature or through testing,

v) the number of antimicrobials to be tested should comply with the guideline used (CLSI/EUCAST/ISO) and at least contain class representatives to ensure the relevance and practicality of AST (see also WHO, 2017).

Periodic review of microorganisms that are currently predictably susceptible to certain antimicrobial agents is recommended to ensure that emergent, unexpected resistance is detected. Emerging resistance may also be suspected following poor response or treatment failure to a standard antimicrobial treatment regime.

3. Antimicrobial susceptibility testing methodologies

The following requirements should be respected:

i) bacteria subjected to AST must be isolated in pure culture from the submitted sample,

ii) standard reference methods should be used for identification so that the subject bacteria are consistently and correctly identified to the genus and/or species level,

iii) bacterial isolates considered to be the most important and other selected isolates, should be stored for future analysis (either lyophilisation or cryogenic preservation at –70°C to –80°C).

The following factors influencing AST methods should be determined, optimised, and documented in a detailed standard operating procedure:

i) once the bacterium has been isolated in pure culture, a standardised concentration of the inoculum must be prepared using a nephelometer or spectrophotometer to ensure a defined number of colony forming units to obtain accurate and repeatable susceptibility results. Bacteria or other organisms used in AST testing should be from a fresh 24-hour culture,

ii) the composition and preparation of the agar and broth media used (e.g. pH, cations, thymidine or thymine, use of supplemented media) should comply with guidelines (CLSI/EUCAST/ISO). Performance and sterility testing of media lots should also be determined and documented as well as the procedures used,

iii) the content, range/interval and concentration of the antimicrobials used (microtitre plates, disk, strip, tablet) should follow guidelines (CLSI/EUCAST/ISO) and be relevant to the species tested,

iv) composition of solvents and diluents for preparation of antimicrobial stock solutions,

v) growth and incubation conditions (time, temperature, atmosphere e.g. CO_2),

vi) agar depth,

vii) the test controls to be used, including the reference organisms used,

viii) the subsequent interpretive criteria (clinical breakpoints, epidemiological cut-off values – ECOFFs).

For these reasons, special emphasis has to be placed on the use of documented procedures and validated, well documented methods, as sufficient reproducibility can be attained only through the use of such methodology.

4. Selection of antimicrobial susceptibility testing methodology

The selection of an AST methodology may be influenced by the following factors:

i) ease of performance,

ii) flexibility,

iii) adaptability to automated or semi-automated systems,

iv) cost,

v) reproducibility,

vi) reliability,

vii) accuracy,

viii) the organisms and the antimicrobials of interest in that particular WOAH Member,

ix) availability of suitable validation data for the range of organisms to be susceptibility tested.

5. Antimicrobial susceptibility testing methods

The following three methods have been shown to consistently provide reproducible and repeatable results when followed correctly (Clinical and Laboratory Standards Institute [CLSI], 2008; Walker, 2007):

i) disk diffusion,

ii) broth dilution,

iii) agar dilution,

5.1. Disk diffusion method

Disk diffusion refers to the diffusion of an antimicrobial agent from a disk or tablet containing a specified concentration of the agent tablets into a solid culture medium (normally Müller–Hinton agar) that has been inoculated with a pure culture (see Section 3). The disk diffusion result is determined by measurement of the diameter of the inhibition zone around the disk, the diameter being proportional to the bacterial susceptibility to the antimicrobial present in the disk.

The diffusion of the antimicrobial agent into the culture media results in a gradient of the antimicrobial. When the concentration of the antimicrobial becomes so diluted that it can no longer inhibit the growth of the test bacterium, the zone of inhibition is demarcated. The diameter of this zone of inhibition around the antimicrobial disk is related to MIC for that particular bacterium/antimicrobial combination; the zone of inhibition correlates inversely with the MIC of the test bacterium. Generally, the larger the zone of inhibition, the lower the concentration of antimicrobial required to inhibit the growth of the organisms. However, this depends on the concentration of antimicrobial agent in the disk and its diffusibility. Antimicrobial agents that are very large molecules diffuse poorly in agar making disk diffusion methods unreliable for these compounds. For this reason disk diffusion methods are not recommended for example for the susceptibility testing of colistin/polymyxin (Matuschek *et al*., 2018).

Note: Disk diffusion tests based solely on the presence or absence of a zone of inhibition without regard to the size of the zone of inhibition are not acceptable AST methodology.

5.1.1. Considerations for the use of the disk diffusion methodology

Disk diffusion is easy to perform, reproducible if standardised, and does not require expensive equipment. Its main advantages are:

i) low cost,

ii) ease in modifying test by changing antimicrobial disks when required,

iii) can be used as a screening test against large numbers of isolates,

iv) can identify a subset of isolates for further testing by other methods, such as determination of MICs.

v) the procedure is controlled by inclusion of appropriate control organisms for which a target zone size range is available (or has been derived) for each of the relevant antimicrobial agents being tested in the disk diffusion test procedure.

Manual measurement of zones of inhibition may be time-consuming. Automated zone-reading devices are available that can be integrated with laboratory reporting and data-handling systems. The disks should be distributed evenly on the agar surface so that the zones of inhibition around

antimicrobial discs in the disc diffusion test do not overlap to such a degree that the zone of inhibition cannot be determined. Generally, this can be accomplished if the discs are no closer than 24 mm from centre to centre, though this is dependent on disk concentration and the ability of the antimicrobial to diffuse in agar. Contamination of culture plates may be harder to detect using automated readers.

The diameter of the zone of inhibition obtained in disk diffusion tests is strongly influenced by the density of the bacterial inoculum applied, underlining the requirement to standardise the inoculum in accordance with guidelines (CLSI, EUCAST, ISO). A denser inoculum than intended will result in reduced zones of inhibition and a sparse inoculum will result in increased zones of inhibition (BSAC [British Society for Antimicrobial Chemotherapy], 2015).

5.2. Broth and agar dilution methods

The aim of the broth and agar dilution methods is to determine the lowest concentration of the antimicrobial that inhibits the visible growth of the bacterium being tested in either broth or on agar (MIC, usually expressed in μg/ml or mg/litre). The range of concentrations tested in broth and agar dilution methods generally includes the breakpoint (clinical or microbiological) with doubling dilutions either side of that value as considered appropriate. However, the MIC does not always represent exactly the concentration which was tested. The 'true' MIC is a point between the lowest test concentration that inhibits the growth of the bacterium and the next lower test concentration. Therefore, MIC determinations performed using a dilution series may be considered to have an inherent variation of ±1 dilution.

Antimicrobial ranges should encompass both the interpretive criteria (susceptible, intermediate and resistant) for a specific bacterium/antibiotic combination and appropriate quality control reference organisms. Target MIC ranges should be available for each antimicrobial agent being tested.

Antimicrobial susceptibility dilution methods are more reproducible than agar disk diffusion which is why broth microdilution is the current reference test method. However, antibiotics are usually tested in doubling dilutions, which can produce inexact MIC data. The continuous range of zone diameter values obtained with disk diffusion can therefore be advantageous in certain circumstances, such as screening large numbers of susceptible isolates.

Any laboratory that intends to use a dilution method and set up its own reagents and antibiotic dilutions should have the ability to obtain, prepare and appropriately maintain stock solutions of reagent-grade antimicrobials, to account for the potency of the antimicrobial (supplied by the manufacturer) and to generate complex working dilutions on a regular basis. Published methods should be consulted. It is then essential that such laboratories use quality control organisms (see below) to assure accuracy and standardisation of their procedures.

5.2.1. Broth dilution

Broth dilution is a technique in which a suspension of a bacterium of a predetermined optimal concentration is tested against varying concentrations of an antimicrobial agent (usually serial twofold dilutions) in a liquid medium of predetermined, documented formulation. The broth dilution method can be performed either in tubes containing a minimum volume of 2 ml (macrodilution) or in smaller volumes using microtitration plates (microdilution). Numerous microtitre plates containing lyophilised or dried prediluted antibiotics within the wells are commercially available. The use of the same batches of microdilution plates may assist in the minimisation of variation that may arise due to the preparation and dilution of the antimicrobials at different laboratories. The use of these plates, with a documented test protocol, including specification of appropriate reference organisms, will facilitate the comparability of results among laboratories.

Due to the fact that most broth microdilution antimicrobial test panels are prepared commercially, this method is less flexible than agar dilution or disk diffusion in adjusting to the changing needs of the surveillance/monitoring programme.

Because the purchase of antimicrobial plates and associated equipment may be costly, this methodology may not be feasible for some laboratories.

5.2.2. Agar dilution

Agar dilution involves the incorporation of varying concentrations of antimicrobial agent into an agar medium, usually using serial twofold dilutions, followed by the application of a defined bacterial inoculum to the agar surface of the plate. This method may be considered the most reliable for MIC determination for some antimicrobials (fosfomycin, mecillinam) and for certain bacteria where broth dilution methods are not well established.

The advantages of agar dilution methods include:

i) the ability to test multiple bacteria, except bacteria that swarm, on the same set of agar plates at the same time,

ii) the potential to improve the identification of MIC endpoints and extend the antibiotic concentration range,

iii) the possibility to semi-automate the method using an inoculum-replicating apparatus. Commercially produced inoculum replicators are available and these can transfer between 32 and 60 different bacterial inocula to each agar plate.

Agar dilution methods also have certain disadvantages, for example:

i) if not automated, they are very laborious and require substantial economic and technical resources,

ii) once the plates have been prepared, they normally should be used within 1–3 weeks depending in quality control (or less, depending on the stability of the antimicrobials tested),

iii) the endpoints are not always easy to read.

Agar dilution is often recommended as a standardised AST method for fastidious organisms (CLSI, 2015), such as anaerobes and *Helicobacter* species.

5.3. Other bacterial AST and specific antimicrobial resistance tests

Bacterial antimicrobial MICs can also be obtained using commercially available gradient strips that diffuse a predetermined antibiotic concentration. However, the use of gradient strips can be expensive and MIC discrepancies can be found when testing certain bacteria/antimicrobial combinations compared with results of other methods (Ge *et al.*, 2002; Rathe *et al.*, 2009). Gradient strip methods are not recommended for testing the susceptibility of the antimicrobial agent colistin because of the large size of this molecule and its poor diffusion in agar (Matuschek *et al.,* 2018).

Regardless of the AST method used, the procedures should be documented in detail to ensure accurate and reproducible results, and appropriate reference and control organisms should always be tested every time AST is performed in order to ensure accuracy and validity of the data.

The appropriate AST choice can be dependent on the growth characteristics of the bacterium in question, as well as the objective of testing. In special circumstances, novel test methods and assays may be more appropriate for detection of particular resistance phenotypes. For example, chromogenic cephalosporin-based tests (CLSI, 2018) (e.g. nitrocefin) may provide more reliable and rapid results for beta-lactamase determination in certain bacteria, whereas inducible clindamycin resistance in *Staphylococcus* spp. may be detected using a disk diffusion method employing standard erythromycin and clindamycin disks in adjacent positions and measuring the resultant zones of inhibition (e.g. D-zone or D-test) (Zelazny *et al.*, 2005).

Similarly, extended-spectrum beta-lactamase (ESBL) (CLSI, 2018) activity in certain bacteria can also be detected by using standard disk diffusion susceptibility test methods incorporating specific cephalosporins (cefotaxime and ceftazidime) separately and in combination with a beta-lactamase inhibitor (clavulanic acid) and measuring the resulting zones of inhibition. Penicillin-binding protein 2a (PBP 2a) can also be detected in methicillin resistant staphylococci with a latex agglutination test (Stepanovic *et al.*, 2006). It is essential that testing of known positive and negative control strains occurs alongside clinical isolates to ensure accurate results.

Susceptibility testing may also be performed using breakpoint values specifically intended to detect particular mechanisms of bacterial resistance of clinical or public health importance, for example resistance to the carbapenems, which are used prudently to treat highly-resistant bacterial in humans (EUCAST [European Committee on Antimicrobial Susceptibility Testing], 2017).

5.4. Future directions in antimicrobial susceptibility/resistance detection

The use of genotypic approaches for detection of antimicrobial resistance genes has been promoted as a way to increase the rapidity and accuracy of susceptibility testing (Cai *et al.*, 2003; Chen *et al.*, 2005). Numerous DNA-based assays are being developed to detect bacterial antimicrobian resistance at the genetic level. The newest and perhaps most state-of-the-art approach is to use genome sequencing to predict antimicrobial resistance phenotypes via identification and characterisation of the known genes that encode specific resistance mechanisms.

Methods that employ the use of comparative genomics, genetic probes, microarrays, nucleic acid amplification techniques (e.g. polymerase chain reaction [PCR]), and DNA sequencing offer the promise of increased sensitivity, specificity, and speed in the detection of specific known resistance genes (Cai *et al.*, 2003; Chen *et al.*, 2005; Perreten *et al.*, 2005). Genotypic methods have been successfully applied to supplement traditional AST phenotypic methods for other organisms including methicillin-resistant staphylococci, vancomycin-resistant enterococci, and detection of fluoroquinolone resistance mutations (Cai *et al.*, 2003; Chen *et al.*, 2005; Perreten *et al.*, 2005). PCR methods have also been described for beta-lactamases, aminoglycoside inactivating enzymes, and tetracycline efflux genes (Cai *et al.*, 2003; Chen *et al.*, 2005; Frye *et al.*, 2010; Perreten *et al.*, 2005).

Technological innovations in DNA-based diagnostics should allow for the detection of multiple resistance genes and/or variants during the same test. The development of rapid diagnostic identification methods and genotypic resistance testing should help reduce the emergence of antimicrobial resistance, by enabling the use of the most appropriate antimicrobial when therapy is initiated. However, DNA techniques have to be demonstrated to be complementary to AST methods and results.

Additionally, new technological advances may facilitate the ability to probe bacterial species for large numbers of antimicrobial resistance genes quickly and cheaply, thereby providing additional relevant data for surveillance and monitoring programmes (Frye *et al.*, 2010). However, despite the new influx of genotypic tests, documented and agreed upon phenotypic AST methods will still be required in the near future to detect emerging resistance mechanisms among bacterial pathogens and to detect and characterise newly discovered mechanisms of resistance for the development and validation of genetic testing. A literature review (Ellington *et al.,* 2017) considered the role of whole genome sequencing (WGS) in antimicrobial susceptibility testing of bacteria and concluded there was insufficient published evidence to support the use of AST via WGS to replace phenotypic AST in clinical settings for all bacterial species, although certain bacteria (e.g. *Salmonella, Staphylococcus aureus*) had been well characterised for that purpose. Subsequently several publications have added support to the use of genetic AST (e.g. McDermott *et al.,* 2016, Zhao *et al.,* 2016). The future of genetic testing in the detection of antimicrobial resistance is promising, but phenotypic testing will remain an important mainstay.

6. Antimicrobial susceptibility breakpoints and zone of inhibition criteria

The primary objective of *in-vitro* AST is to predict how a bacterial pathogen may respond to an antimicrobial agent *in vivo.* The results generated by bacterial *in-vitro* antimicrobial susceptibility tests, regardless of whether disk diffusion or dilution methods are used, are generally interpreted and reported as resistant, susceptible or intermediate to the action of a particular antimicrobial by applying clinical breakpoints. No single formula for selection of optimal breakpoints has been established. The process involves a review of existing data and is influenced by the methods used to select appropriate breakpoints.

Generally, antimicrobial susceptibility breakpoints are established by national standards organisations, professional societies or regulatory agencies. The relevant documents should be consulted. However, there can be notable differences in breakpoints for the same antimicrobial agent within and among countries due to differences between standards setting organisations and regulatory agencies and because of regional or national differences in dosing regimens (Brown & MacGowan, 2010; de Jong *et al.*, 2009; Kahlmeter *et al.*, 2006).

As mentioned previously, antimicrobial susceptibility testing results should be recorded quantitatively:

i) as distribution of MICs in mg/litre or μg/ml,

ii) or as inhibition zone diameters in millimetres.

The following two primary factors enable a bacterial isolate to be interpreted as susceptible or resistant to an antimicrobial agent:

i) The development and establishment of quality control ranges (CLSI, 2015), for disk diffusion or dilution testing, for quality control reference microorganisms.

   Establishment of quality control ranges for control organisms is essential for validating test results obtained using a specific AST method. The allowable interpretive category ranges for reference control organisms should be established in addition to determining breakpoints for susceptibility or resistance. The use of reference organisms is a quality control and quality assurance activity.

ii) The determination of the appropriate interpretive criteria regarding establishment of breakpoints (CLSI, 2015).

   This involves the generation of three distinct types of data:

   a) MIC population distributions of the relevant microorganisms,

   b) pharmacokinetic parameters and pharmacodynamic indices of the antimicrobial agent,

   c) results of clinical trials and the outcome of treatment of clinical cases of disease.

The development of a concept known as 'microbiological breakpoints', or 'epidemiological cut-off values' (the highest MIC value for the bacterium and antimicrobial agent under consideration, where the bacterium is devoid of any phenotypically expressed resistance to that antimicrobial agent), may be more appropriate for some antimicrobial surveillance programmes. Epidemiological cut-off values are derived by examining MIC population distributions for specific bacterial species and antimicrobials performed at several laboratories according to a standardised broth microdilution method. Bacterial isolates that possess any acquired phenotypic resistance (that is, have an MIC above the epidemiological cut-off value) and therefore deviate from the normal wild-type fully-susceptible population are designated as non-wild type (also termed microbiologically resistant) and shifts in susceptibility to the specific antimicrobial/bacterium combination can thus be monitored (Kahlmeter, 2015; Kahlmeter *et al.*, 2006; Turnidge *et al.*, 2006). There is a great advantage in the recording of quantitative susceptibility data in that data may be analysed according to clinical breakpoints as well as by using epidemiological cut-off values.

The development of breakpoint criteria for disk diffusion tests usually involves comparing disk diffusion data against dilution data by creating a scattergram of the bacterial population distribution (representative bacterial isolates), by plotting the zone of inhibition against the logarithm to the base 2 of the MIC for each bacterial isolate for an individual bacterial species. The selection of breakpoints is then based on multiple factors, including regression line analysis that correlates MICs and zone diameters of inhibition, bacterial population distributions, error rate bounding, pharmacokinetics, and ultimately, clinical verification.

7. Antimicrobial susceptibility testing guidelines

A number of national standards and guidelines are currently available. International standards and guidelines for antimicrobial susceptibility testing and subsequent interpretive criteria throughout the world are:

Clinical Laboratory and Standards Institute (CLSI, 2018),
European Committee on Antimicrobial Susceptibility Testing (EUCAST, 2017).

At this time, only the CLSI has developed protocols for susceptibility testing of bacteria of animal origin and determination of interpretive criteria (CLSI, 2018). A veterinary sub-committee (VETCAST) has also been set up under the umbrella of EUCAST. However, protocols and guidelines are available from a number of standards organisations and professional societies, including those listed above for susceptibility testing for similar bacterial species that cause infections in humans. It is possible that such guidelines can be adopted for susceptibility testing for bacteria of animal origin, but each country must evaluate its own AST standards and guidelines. Additionally, efforts focusing on both standardisation and harmonisation of susceptibility/resistance breakpoints on an international scale are progressing. These efforts have primarily focused on the adoption of the standards and

guidelines of CLSI and EUCAST, which provide laboratories with methods and quality control values enabling comparisons of AST methods and generated data (CLSI, 2018; Kahlmeter *et al.*, 2006). For those WOAH Members that do not have standardised AST methods in place, the adoption of either set of standards would be an appropriate initial step towards acceptable methods and harmonisation.

Many bacteria that cause disease in aquatic animals require growth conditions (e.g. lower temperatures, supplemented or semisolid media) that may vary considerably as compared to terrestrial bacterial pathogens. This necessitated the need for the development of antimicrobial testing methods for bacteria isolated from aquatic species. Further information with regards to methods for disk diffusion or broth dilution antimicrobial susceptibility testing for bacteria isolated from aquatic animals can be referenced in two CLSI documents (CLSI, 2006; 2014b). Further information with regards to methods for disk diffusion or broth dilution antimicrobial susceptibility testing for infrequently isolated or certain fastidious bacteria (e.g. *Campylobacter*, *Pasteurella*) can also be referenced in the CLSI M45-A document (CLSI, 2015).

As a first step towards comparability of monitoring and surveillance data, Members should be encouraged to strive for harmonised and standardised programme design (Brown & MacGowan, 2010; Kahlmeter *et al.*, 2006; White *et al.*, 2001). Data from countries using different methods and programme design may otherwise not be directly comparable (Brown & MacGowan, 2010). Notwithstanding this, data collected over time in a given country may at least allow the detection of emergence of antimicrobial resistance or trends in prevalence of susceptibility/resistance in that particular country (Petersen *et al.*, 2003). However, if results achieved with different AST methods are to be compared, then comparability of results must be demonstrated and consensus on interpretation achieved. This will be best accomplished by the use of accurate and reliable documented AST methods used in conjunction with monitoring of AST performance while using well characterised reference microorganisms among participating laboratories.

Table 1. Phenotypic susceptibility testing methods available and their features

Susceptibility testing method	International standard available	Published methods available	Use in national surveillance programmes	Use in susceptibility testing for therapeutic purposes	Breakpoints that may be applied	Test output	Comparability of outputs	Features
Broth (micro) dilution MIC determination	Yes (ISO 20776-1), CLSI, EUCAST	Yes (CLSI, EUCAST)	Yes, broth microdilution MIC determination is preferred	Yes	Clinical breakpoints or epidemiological cut-off values (ECOFFs)	MIC	High	Current reference method. Recording MIC values allows interpretation of the test outputs using different breakpoints (e.g. clinical breakpoint or ECOFF), as well as re-evaluation of historical data if changes occur to breakpoints and evaluation of shifts in MIC. Numerous national surveillance programmes adopt this method. The MIC value can sometimes indicate the likely mechanism of resistance (e.g. high-level amikacin resistance and rRNA methylases) or provide an epidemiological marker. Currently, this is the only method suitable for determining susceptibility to colistin.
Agar dilution MIC determination	No	Yes (CLSI, EUCAST)	Not widely used	Yes	Clinical breakpoints or ECOFFs	MIC	Dependent on congruity of methods used	Reference method. The breakpoints appropriate for broth dilution may not be directly applicable to agar dilution. Currently used in particular for testing certain fastidious organisms.
Breakpoint method	No	Yes (scientific literature)	Not widely used	Yes	The test is performed at a set breakpoint	Resistant or susceptible at selected breakpoint	Dependent on congruity of methods used	Changes to breakpoints in this method result in the inability to interpret historical data. Shifts in susceptibility within the S or R categories cannot be detected. The breakpoint method relies on the growth or absence of growth of bacteria in broth or on agar containing an antimicrobial at a single (breakpoint) dilution.
Gradient strip method	No	Yes (manufacturer)	Not widely used	Yes	Clinical breakpoints or ECOFFs	MIC	High	Provide a convenient alternative method of determining MIC with minimal additional equipment required.
Disc diffusion test	No	Yes (CLSI, EUCAST) A number of different methods are available. These are not in general equivalent.	May be used, but broth microdilution MIC determination is preferred	Yes	Clinical breakpoints (ECOFFs are also available for the EUCAST disc diffusion method).	Diameter of zone of inhibition, interpreted as resistant or susceptible according to test guidelines	Dependent on congruity of methods used	Frequently used to provide an indication of susceptibility for therapeutic purposes. Versatile in that different discs can be used, according to the antimicrobials authorised for treatment. Different methods are not usually equivalent (zone sizes obtained using one method cannot be interpreted using criteria from another, different method). The collection of zone size data can allow shifts in susceptibility to be detected. Disc diffusion methods may be harmonised to a degree with other methods, by using the same breakpoint.

The susceptibility testing method selected should provide details of the method, appropriate controls and quality control ranges and breakpoints. The comparability of outputs obtained in surveillance programmes is not only dependent on the laboratory methodology used but is also dependent on the target population of livestock included in the study and method of sampling.

8. Comparability of results

To determine the comparability of results originating from different surveillance systems, results should be reported quantitatively including information on the performance of the methods, the reference organisms and breakpoints used and the antimicrobial.

AST data, consisting of cumulative and ongoing summary of susceptibility patterns (antibiograms) among clinically important and surveillance microorganisms should be created, recorded and analysed periodically at regular intervals (CLSI, 2014a). Data must also be presented in a clear and consistent manner so that both new patterns of resistance can be identified and atypical findings confirmed or refuted. This data should be available on a central data bank and published yearly.

Cumulative AST data will be useful in monitoring susceptibility/resistance trends in a region over time and assessing the effects of interventions to reduce antimicrobial resistance.

9. Quality control (QC) and quality assurance (QA)

Quality control/quality assurance systems should be established in accordance with chapter 1.1.5 in laboratories performing AST:

i) quality control refers to the operational techniques that are used to ensure accuracy and reproducibility of AST,

ii) quality assurance includes, but is not limited to, monitoring, record keeping, evaluating, taking potential corrective actions if necessary, calibration, and maintenance of equipment, proficiency testing, training and QC. A QA programme helps ensure that testing materials and processes provide consistent quality results.

The following components should be determined and monitored:

i) precision of the AST procedure,

ii) accuracy of the AST procedure,

iii) qualifications, competence, and proficiency of the laboratory personnel, as well as the personnel that interpret the results and those that are involved in monitoring of antimicrobial resistance,

iv) performance of the appropriate reagents.

The following requirements should be respected:

i) Strict adherence to specified and documented techniques in conjunction with quality control (i.e. assurance of performance and other critical criteria) of media and reagents.

ii) Record keeping of:

   a) lot numbers of all appropriate materials and reagents,

   b) expiration dates of all appropriate materials and reagents,

   c) equipment calibration and monitoring,

   d) critical specifications for AST performance (reference results, time, temperature etc.).

iii) The appropriate reference microorganism(s) should always be used regardless of the AST method employed.

iv) Reference microorganisms are to be obtained from a reliable source for example, from the American Type Culture Collection (ATCC®), reliable commercial sources, or institutions with demonstrated reliability to store and use the organisms correctly.

v) Reference microorganisms should be catalogued and well characterised, including stable defined antimicrobial susceptibility phenotypes. Records regarding these reference organisms should include the

established resistant and susceptible ranges of the antimicrobials to be assayed, and the reference to the method(s) by which these were determined.

vi) Laboratories involved in AST should use the appropriate reference microorganisms in all AST testing.

vii) Reference strains should be kept as stock cultures from which working cultures are derived and should be obtained from national or international culture collections. Reference bacterial strains should be stored at designated centralised or regional laboratories. Working cultures should not be subcultured from day to day as this introduces contamination and the method of producing working cultures should ensure that stock cultures are rarely used. This may be accomplished with the production of an intermediate stock of cultures derived from the original cultures that are used to crate day-to-day working cultures.

viii) The preferred method for analysing the overall performance of each laboratory should test the working stock of the appropriate reference microorganisms on each day that susceptibility tests are performed.

Because this may not always be practical or economical, the frequency of such tests may be reduced if the laboratory can demonstrate that the results of testing reference microorganisms using the selected method are reproducible. If a laboratory can document the reproducibility of the susceptibility testing methods used, testing may be performed on a weekly basis. If concerns regarding accuracy, reproducibility, or method validity emerge, the laboratory has a responsibility to determine the cause(s) and repeat the tests using the reference materials. Depending on the cause(s), daily reference material use and any other corrective action may be re-initiated.

ix) Reference microorganisms should be tested each time a new batch of medium or plate lot or batch of disks is used and on a regular basis in parallel with the microorganisms to be assayed.

x) Appropriate biosecurity issues should be addressed in obtaining and dispersing microorganisms to participating laboratories.

10. External proficiency testing

Laboratories should participate in external quality assurance and/or proficiency testing programmes in accordance with chapter 1.1.5. Laboratories are also encouraged to participate in international inter-laboratory comparisons (e.g. WHO External Quality Assurance System) (Hendriksen *et al.*, 2009). All bacterial species subjected to AST should be included.

National reference laboratories should be designated with responsibility for:

i) monitoring the quality assurance programmes of laboratories participating in surveillance and monitoring of antimicrobial resistance,

ii) characterising and supplying to those laboratories a set of reference microorganisms,

iii) creating, managing, and distributing samples to be used in external proficiency testing,

iv) creating a central database available on the internet (e.g. European Antimicrobial Resistance Surveillance System [EARSS]) that contains the different susceptibility/resistance profiles for each bacterial species under surveillance.

11. Conclusion

Although a variety of methods exist, the goal of *in-vitro* antimicrobial susceptibility testing for clinical veterinary purposes, surveillance and monitoring is the same: to provide a reliable predictor of how a microorganism is likely to respond to antimicrobial therapy in the infected host. This type of information aids the clinician in selecting the appropriate antimicrobial agent, provides data for surveillance, and aids in developing antimicrobial judicious use policies (WOAH, 2018).

In-vitro antimicrobial susceptibility testing can be performed using a variety of formats, the most common being disk diffusion, agar dilution, broth macrodilution, broth microdilution, and a concentration gradient test. Each of these procedures requires the use of specific testing conditions and methods, including media, incubation conditions and times, and the identification of appropriate quality control organisms along with their specific QC ranges. It is essential that AST methods provide reproducible results in day-to-day laboratory use and that the data be comparable with those results obtained by an acknowledged 'gold standard' reference method. In the absence

of standardised methods or reference procedures, antimicrobial susceptibility/resistance results from different laboratories cannot be reliably compared.

The use of genotypic approaches for detection of antimicrobial resistance genes has also been promoted as a way to increase the rapidity and accuracy of susceptibility testing. New technological advances in molecular techniques (e.g. microarray) may facilitate the ability to probe bacterial species for large numbers of antimicrobial resistance genes quickly and cheaply, thereby providing additional relevant data into surveillance and monitoring programs (Ojha & Kostrzynska, 2008; Poxton, 2005). Standardised phenotypic AST methods will still be required to detect novel and emerging resistance mechanisms among bacterial pathogens and to validate their detection via genetic techniques (Ellington *et al.,* 2017).

CHAPTER 2.1.2.

BIOTECHNOLOGY ADVANCES IN THE DIAGNOSIS OF INFECTIOUS DISEASES

INTRODUCTION

Modern methods of livestock production and increased global trade demand the development of early warning diagnostic platforms, global capacity, effective assays and diagnostic harmonisation to enhance livestock productivity and health and to facilitate trade in healthy animals as the basis of the global One Health initiative.

The risk of pathogen-transfer between countries or continents has increased markedly in recent years, due to several factors, such as increased national and international movement of people, animals, food and feed products, and various goods, and climatic changes, causing new epidemiological scenarios and threats. This new situation highlights the requirement for the development and application of a wide range of powerful novel diagnostic methods that can detect spreading pathogens very rapidly, with high diagnostic specificity and sensitivity.

The purpose of this chapter is to provide general information and updates on the most important biotechnology-based methods, currently used in our diagnostic laboratories. For further information, two issues of the WOAH Scientific and Technical Review *concerned with biotechnology and the diagnosis of animal diseases are available on the WOAH website (https://www.woah.org/en/what-we-do/publications/scientific-and-technical-review/; Potential applications of pathogen genomics: Volume 35, Issue 1, 2016; Biotechnology applications in animal health and production: Volume 24, Issue 1, 2005).*

A. TECHNIQUES FOR THE DETECTION AND ANALYSIS OF NUCLEIC ACIDS

The direct detection and amplification of specific nucleic acid sequences in the genomes of pathogens have been shown to have considerable advantages. Polymerase chain reaction (PCR)-based technologies have revolutionised the diagnosis of infectious diseases. DNA amplification platforms are highly sensitive, specific, rapid and robust. The platforms are also cost-effective and adaptable to automation and therefore ideal for high-throughput screening. The equipment required is highly adaptable to the detection of many different targets, however the quality of the specimens is key to successful use of these technologies.

1. Nucleic acid extraction

An important initial step in most molecular diagnostic procedures is the extraction of 'clean' nucleic acid mixtures from the clinical sample. While it is relatively easy to extract DNA from bacterial cultures or blood, it is technically more challenging to prepare suitable material from field specimens, such as faeces, internal organs or aborted fetuses. Care during sampling in the field and in laboratory processing during the extraction of nucleic acids is important to avoid cross contamination of specimens, leading to false positive results. For this reason, nucleic acid extraction should be performed using strict working procedures, in an isolated room separated from nucleic acid amplification procedures.

Nucleic acid isolation and purification consists of three main steps: disruption of cells, removal of proteins and contaminants, and recovery of nucleic acid suitable for analysis. There are numerous methods of nucleic acid extraction, including manual extraction using phenol-chloroform and guanidinium thiocyanate to concentrate DNA in a hydrophilic phase, centrifugal spin column-based elution where nucleic acid binds to a solid phase such as silica and proteins are removed with the aid of centrifugation and magnetic bead extraction where the nucleic acid binds to magnetic particles while the proteins are washed away. While extraction methods may vary in the relative yield

and purity of the targeted nucleic acids, effective and reproducible extraction is an essential part of nucleic acid detection and thus pathogen detection. PCR, or other methods described below, can amplify and detect the specific target, but the quality of the starting material is an inherent part of the detection process.

Several specialised extraction methods for particular types of samples and tissues are now commercially available either as manual or automated systems for robotic workstations. The development and accessibility of the robotic extraction platforms not only minimises the risk of contamination, but also enables processing of large numbers of samples under constant reaction conditions with minimal operator manipulation. Consequently, these platforms have contributed to the establishment of high-throughput, robust diagnostic assays, shortening the processing time required per sample from hours to minutes (Belák *et al.,* 2009; Oberacker *et al.,* 2019). These are destined to improve the reliability of nucleic acid extraction from different specimens, but it remains a challenging area.

As an alternative to nucleic acid extraction, biotechnologists are increasingly focusing on PCR-inhibitor resistant polymerases and novel amplification assays, which are now available to directly amplify nucleic acids from pathological specimens without the requirement for extraction steps (Pavsic *et al.,* 2016).

2. Conventional polymerase chain reaction (PCR) and real-time PCR

PCR is a widely used, highly sensitive diagnostic tool for detecting pathogen-specific nucleic acid sequences in host tissues and vectors. Over the past 30 years, PCR has revolutionised the diagnostic process, allowing rapid, highly sensitive and specific detection of a wide range of pathogens.

PCR can identify and amplify a specific, selected target region of nucleic acid from a complex mixture of heterogenous sequences (Saiki *et al.,* 1988). PCR achieves *in-vitro* amplification by exploiting natural DNA replication mechanisms, using a succession of cyclic incubation steps at different temperatures. Amplification facilitates the detection of target nucleic acid sequences within a sample, even when only a small number of targets were present originally.

Diagnostic PCR is performed on nucleic acids extracted from clinical samples. The heterogenous sample DNA is first heat-denatured to separate the two complementary strands, thereby creating a single-stranded template. Specific primers are then used to identify the target regions for amplification. Primers are short, synthetic, single-stranded DNA molecules complementary to the target sequences. If the target sequence is present in the sample, the primers will anneal to these regions as the temperature cycle cools. Following binding, the cycle enters an intermediate temperature phase in which bound primers enable extension of the target sequence by DNA polymerase. Once the polymerase has synthesised a new complementary strand of DNA, the product is separated from the template by heating to a higher temperature and the cycle repeated.

These cycles are repeated, usually between 35–50 times, resulting in the amplification of target DNA sequences. Each cycle has the potential to double the number of targets from the previous cycle leading to the exponential increase in target DNA that gives the method its high sensitivity. The key to the amplification of target DNA sequences by the PCR is the selection of paired primers that, when extended, will create additional reciprocal primer-annealing sites for primer extension in subsequent cycles. To detect RNA (e.g. RNA viruses), a complementary DNA (cDNA) copy of the RNA must first be made using reverse transcription (RT). The cDNA then acts as a template for amplification by PCR. This technique is referred to as reverse transcription PCR (RT-PCR).

Once amplified, the target sequence can be detected. Amplified products are detected most frequently using methods that also help to confirm the identity of the PCR products, including:

i) Methods that define their characteristic size (such as gel electrophoresis)

ii) DNA probes (see below)

iii) High resolution melting (see Section A.2.1)

iv) Fluorescence-based detection systems (real-time technology)

v) Nucleotide sequencing technologies

Increasingly, since the advent of automated cycle sequencing techniques, identification is made more and more frequently via PCR techniques and agent characterisation by direct sequencing of the PCR products.

To provide robust, reproducible results, the PCR protocols should be carefully designed, optimised and fully validated. Chapter 2.2.3 *Development and optimisation of nucleic acid detection methods* provides comprehensive information and guidance on such assays.

To expand its utility in veterinary diagnostics and pathogen identification, PCR has been modified extensively over the years. Traditional PCR requiring detection at the end-point of the reaction, typically by agar gel electrophoresis, has been largely superseded by detection while the reaction is occurring i.e. real-time PCR. The most common variations; the main advantages and the limitations of PCR technologies are summarised in Table 1.

Table 1. Summary of commonly used variations in PCR techniques, their advantages and disadvantages

PCR: amplifies a selected region of target nucleic acid in a sample			
Variations	**Details**	**Advantages**	**Disadvantages**
Nested PCR	Two rounds of PCR, with the second round further amplifying a pre-amplified genomic fragment from the first round. Generally superseded by the real-time PCR	High sensitivity	High risk of contamination as it is not a closed system and cross-contamination or carry-over may occur via handling of amplified products
Consensus PCR	Targets a conserved genomic region in a group of pathogens	Can identify new but closely related pathogens	Not specific, may require further characterisation
Real-time PCR	Results of amplification are detected in real time, through fluorescence of a region-specific probe. Quantification is possible, if standards with known copy numbers are used in the run (hence the alternative name of quantitative PCR)	Highly sensitive and highly specific; decreased risk of contamination as the system is closed and there is no post-amplification manipulation	Cost (probes; platform). Risk of false negatives with highly mutable agents: primer probe sets can be designed to be highly target specific or universal to detect sequences conserved across lineages and strains
Multiplex real-time PCR	Detects multiple targets at once	Allows for screening numerous pathogens in one assay	Sensitivity can be compromised. Limited by the number of different fluorescent dyes available

2.1. High resolution melting

For DNA organisms such as parasites and bacteria, and for DNA viruses, the use of high-resolution melting (HRM) allows the genotyping of subtypes of a pathogen based on nucleotide differences. HRM is a post-PCR analysis method for analysing the melting (dissociation) of the PCR products in the presence of improved double-stranded DNA-binding dyes. As most real-time PCR machines have integrated this feature, HRM represents a cost-effective method of choice as no labelled probe is required. It is possible to increase the specificity and genotyping accuracy of HRM methods by using unlabelled probes to interrogate a short segment of the PCR amplicon, where the targeted mutation is present. The unlabelled probes must be blocked at the 3'-end to prevent polymerase extension. HRM techniques can be used in singleplex or multiplex format for the simultaneous detection and differentiation of species within the same genus (Banowary *et al.,* 2015; Gelaye *et al*., 2013), drug-resistance screening (Loiacono *et al.,* 2017) or differential diagnosis (Gelaye *et al.,* 2017).

2.2. Mass-tag PCR

Until recently, the detection of amplified target sequences in a real-time PCR assay relied on the use of various chemistries, such as intercalating dyes, hydrolysis probes, molecular beacons, primer probe energy transfer (PriProET), scorpion primers, dual hybridisation probes and dye-labelled oligonucleotide ligation (Belák *et al.,* 2009). The availability of detection methods limited the number of different targets (and thus, different pathogens) that could be detected simultaneously in a multiplex PCR. Mass-tag PCR assays have been developed to overcome this limitation.

In a mass-tag, multiplex PCR assay, the various primers are marked with tags of known, but different, molecular weights. After amplification of the targeted DNA fragments, the tags are released using UV light and subsequently measured using mass spectrometry. This approach enables detection of a far larger range of amplified DNA targets than previously possible, as the assay is not limited to the number of dyes available. This allows a single assay to simultaneously test for a large panel of diseases. Application of the mass-tag PCR assay has been proven already in the differential diagnosis of syndromic diseases (respiratory, haemorrhagic, enteric pathogens, meningitis/encephalitis syndrome) and in the detection of new clades of pathogens (Lipkin, 2010). A modification of this method uses matrix-assisted laser desorption-ionisation (MALDI), which directly measures the molecular weights of the PCR products and compares them with known databases (Angeletti, 2017; Jang & Kim, 2018).

2.3. Digital PCR (dPCR)

In recent years there has been renewed interest in the application of digital PCR (dPCR), where single copies of target DNA and RNA are isolated and individually amplified by PCR. The technique was first described in the 1990s and has since been revitalised due to progress in chemistry and equipment development. The distinctive feature of dPCR is the separation of the reaction mixture into thousands to millions of partitions, which is followed by real-time or end-point detection (conventional PCR) of the amplification. Target sequences are distributed into partitions according to the Poisson distribution model, thus allowing accurate and absolute quantification of the target from the ratio of positive partitions against all partitions at the end of the reaction. This omits the need to use reference materials with known target concentrations and increases the accuracy of quantification at low target concentrations compared with real-time PCR. dPCR has also shown higher resilience to inhibitors in many different types of specimens (Gutierrez-Aguirre *et al.,* 2015). Several research papers have been published on the application of dPCR to the detection and quantification of animal pathogens such as African swine fever virus and pseudorabies virus, demonstrating increased sensitivity and linearity (Ren *et al*, 2018; Wu *et al,* 2018).

2.4. Portable real-time PCR machines

The development of portable real-time PCR machines and assays raises the prospect of these techniques being used for rapid (less than 2 hours) diagnosis of disease outbreaks in the field. However, the isothermal amplification techniques described below may be better, as these require less complex and costly equipment.

3. Isothermal amplification

Isothermal amplification technologies offer the advantage of omitting thermocycling, enabling DNA amplification at a constant temperature. Consequently, the required equipment is less complex and therefore cheaper. The basic principle of this technology has been developed, resulting in several distinct methodologies (Gill & Ghaemi, 2008).

The most widely used method is the loop-mediated isothermal amplification (LAMP) method, which deploys four or more primers forming a stem-loop DNA by self-primed DNA synthesis and a DNA polymerase with strand displacement activity. The result of the amplification process is the production of loops at the ends of the complementary strands, which are continually extended. The amplification process is indicated by either the occurrence of turbidity in the reaction mixture, the generation of a fluorescent signal using fluorescent dyes (Gill & Ghaemi, 2008) or, if primers are biotinylated, the reaction products can be observed using lateral flow devices (see Section B.3 Immunochromatography). The process is also less prone to inhibition from contaminants compared with PCR; however, protocols based on this technology might be difficult and complex to develop. Isothermal amplification is less suitable for multiplex assays than PCR, as the potential for primer dimer formation and/or competitive reactions is higher and the assay design is more difficult in certain cases.

4. Analysis by restriction fragment length polymorphisms (RFLP) and related DNA-based approaches

The restriction fragment length polymorphisms (RFLP) method allows individual genomes to be identified based on unique patterns caused by restriction enzymes cutting in specific regions of DNA. The RFLP approach is based on the fact that the genomes of even closely related pathogens are defined by variation in sequences. For example, the linear order of adjacent nucleotides comprising the recognition sequence of a specific restriction enzyme in one

genome may be absent in the genome of a closely related strain or isolate. The RFLP procedure consists of digesting the pathogens' nucleic acid (DNA or PCR products) with one or a panel of restriction enzymes and then separating the DNA fragments by agarose gel electrophoresis to determine the number of fragments and their relative sizes. A restriction enzyme is an endonuclease that recognises and cleaves double-stranded DNA at specific nucleotide sequences called restriction sites (Loza-Rubio *et al.,* 1999).

Pulsed-field gel electrophoresis (PFGE) can be used for the separation of large (up to megabase size) fragments of DNA and can be a useful adjunct to the basic RFLP analysis. These technologies are extensively used in the official programmes for detection and discrimination of food-borne pathogens (*Escherichia coli* O157:H7, *Salmonella, Shigella, Listeria*, or *Campylobacter*) worldwide (https://www.cdc.gov/pulsenet/).

RFLPs have a clear value for use in epidemiological studies, however, an RFLP difference may not be functionally significant. Although the RFLP and PCR-RFLP are much less powerful compared with the modern sequencing technologies, they are relatively inexpensive, easy to perform and sufficiently descriptive for epidemiological investigations of outbreaks and identification of individual strains of pathogens.

5. Genome sequencing

In recent times, the cost of sequencing has reduced and genome sequencing has become increasingly important in the detection and characterisation of pathogen nucleic acid in diagnostic samples. Genome sequencing involves determining the order in which nucleic acid bases occur in a gene. Sequencing of PCR products targeting an informative region of a gene is particularly useful for pathotyping various organisms. For example, the sequence analysis of influenza virus A haemagglutinin gene is commonly used to locate the cleavage site and thereby classify the virus as highly pathogenic or low pathogenic influenza. Complete genome sequencing is currently the ultimate discriminatory procedure for pathogen identification. Since 1977, the Sanger method (Sanger *et al.,* 1977) has dominated DNA sequencing, although recent advances in high-throughput, next generation sequencing are revolutionising this approach.

Genome sequencing is a complex process. The basic principle is cycle sequencing of targeted DNA fragments with labelled di-deoxy nucleotides, which halt the elongation on binding. Each of the four di-deoxy nucleotides is labelled with a different fluorescent dye, enabling distinction between individual di-deoxy nucleotides. During the PCR process, these labelled di-deoxy nucleotides bind to the DNA fragments wherever their complementary base pairs exist. Once bound, they block further elongation of the DNA fragment. This process creates a mixture of DNA fragments, each ending with a defined nucleotide. The reaction mixture is then analysed using capillary electrophoresis, which separates the fragments by length and reads the fluorescence of each fragment. Analytical software is then used to convert the specific fluorescence signals into a nucleotide sequence.

Genome sequencing allows the analysis of pathogens detected during the diagnostic process. Such analyses include:

i) Identifying pathogenic strains to facilitate the implementation of appropriate control efforts and policies and where indicated, the update of vaccines and development of specific diagnostic tests (Beerens *et al.,* 2017; Busquets *et al.,* 2019).

ii) Evaluating the genetic similarity of isolates to other pathogens of the same species (subtype), to determine their phylogenetic properties or to determine the origin of an outbreak/infection. This can be valuable in the epidemiological analysis of outbreaks.

Importantly, conventional sequencing methods can be used to detect and characterise newly emerging pathogen strains. This overcomes one of the major limitations of PCR-based methods, which require known primers for pathogen detection. For example, sequencing is commonly used to identify a new virus within a family by using degenerate primers (a mix of similar but not identical primers) to amplify a gene common to that virus family, followed by sequencing of the PCR amplicon. Similarly, universal primers that anneal to a conserved sequence can be used to amplify and sequence genes in all bacterial species; the most common application is the use of 16S rRNA gene for bacterial identification (Cai *et al.,* 2014).

Advantages and limitations of the various sequencing techniques commonly applied in diagnostics are summarised in Table 2.

Table 2. Summary of commonly used variations of nucleic acid sequencing techniques, their advantages and disadvantages

Sequencing: determines the nucleotide composition of a selected region of target nucleic acid in a sample			
Variations	**Details**	**Advantages**	**Disadvantages**
Sanger sequencing (also known as di-deoxy sequencing)	DNA fragments from a PCR product are labelled with di-deoxy nucleotide, which can be detected through fluorescence	Highly specific Cost effective for short lengths of DNA Quick and simple work flow and analysis	Sequence length is limited and has no depth. For one sequencing reaction, only one sequence read is generated
High throughput sequencing (HTS) also known as next generation sequencing (NGS) and massive parallel sequencing (MPS)	Genomes are fragmented, and universal adapters and primers are used to generate sequence. HTS is enabling the following types of studies: • Whole genome sequencing • Pathogen discovery (*de novo* sequencing) • Metagenomics • Microbiome detection • Transcriptome detection	No prior knowledge of target is required as the reaction is primer independent Can analyse multiplex samples, using barcodes, which brings the cost down	Cost Requires large data storage and deep bioinformatic analysis, as the amount of data generated is enormous Can take several days to get results however this is offset by the large amount of data generated (e.g. whole genomes) Access to bioinformatics skills and data libraries can be problematic

5.1. High throughput sequencing (HTS) and mobile technologies

High throughput sequencing (HTS) is the term used to describe highly parallel sequencing methods. These methods produce data at the genome level and provide greater diagnostic opportunities compared with conventional sequencing (Belák *et al.,* 2009; Lipkin, 2010). Although various instruments are available, each with its own sequencing methods, the so-called second-generation sequencing technologies share the same general strategy, consisting of clonal amplification of DNA templates followed by sequencing in massively parallel sequencing reactions to produce thousands or millions of reads, ranging in length from 50 to 700 base pairs. These reads are subsequently assembled into longer sequences, known as contigs, using bioinformatics tools (see Chapter 1.1.7 *Standards for high throughput sequencing, bioinformatics and computational genomics*). The availability of bench-top versions of these instruments with reduced costs has made HTS accessible to average-sized laboratories for pathogen identification and characterisation. These new technologies have not only increased the speed of sequencing but also reduced its cost radically. As a consequence, these sequencing methods are becoming ever more significant tools in pathogen detection and definition.

Another application of HTS is whole genome sequencing of infectious agents. HTS allows the assembly of the complete genome or genome segment and reveals reassortment or recombination events and virulence markers. HTS can be used to perform deep re-sequencing of viral sequences within single specimens to assess the evolutionary dynamic (Granberg *et al.,* 2016). Phylogenetic studies and tracing the source of infections can also be undertaken using HTS. However, most HTS platforms produce short reads and so have widely accepted limitations in the *de novo* assembly of new genomes. In this context, a third generation of sequencing methodology producing longer read lengths but lower throughput, provides a means to increase the resolution of the genome assembly, thus enabling more efficient *de novo* sequencing of microbial genomes (Levy & Myers, 2016). At present, portable devices in a flash-drive format are available and can produce reads of 5–50 kb (Granberg *et al.,* 2016). Although the error rate of these instruments, 5–20%, looks very high, the hybrid assembly of short reads from second generation sequencing platforms facilitates the *de novo* assembly of novel microbial genomes. Today, a common technology applied by the portable sequencing devices relies on the principles of nanopore sequencing, which is based on measuring changes in electrical properties as the DNA molecule traverses a pore. These electrical changes are then used to identify the exact DNA base going through the pore.

5.2. Multilocus sequence typing

Multilocus sequence typing (MLST) is a method of sequencing used in pathogen typing and epidemiological studies. Using this approach, fragments of a number of gene targets are amplified by PCR and sequenced. For each locus, unique alleles are assigned arbitrary numbers and, based on the allelic profile, the sequence type is determined. Most MLST methods give highly reproducible results due to the international harmonisation of the nomenclatures; allele sequences and profiles are available in large central databases with companion on-line analysis tools.

6. Metagenomics

Metagenomics refers to culture-independent applications of HTS for investigating the complete viral and microbial genetic composition (microbiome) of samples (Bexfield & Kellam, 2011). Significantly, it is an unbiased approach as organisms are not selected by favourable culture methods (or deselected by unfavourable conditions) and does not require prior knowledge. It is important to consider that without targeted amplification, the metagenomic technologies are less sensitive for pathogen-detection compared with PCR-based methods. However, they are being used more frequently in diagnostic laboratories, because, by detecting a wide range of infectious agents simultaneously, they are powerful diagnostic tools. These technologies have also made it possible to identify pathogens more rapidly, including pathogens that can be difficult to identify by cultivation *in vitro* (Hoper *et al.,* 2017).

From a diagnostic viewpoint, the capacity to detect a wide range of infectious agents simultaneously (Belák *et al*. 2013) is a significant advantage of metagenomic technologies. Some of the agents identified may be novel and metagenomic approaches, accompanied by bioinformatics, have led to the discovery of a high number of infectious agents, including novel bocaviruses, Torque Teno viruses, astroviruses, rotaviruses and kobuviruses in porcine disease syndromes and new virus variants in honey bee populations. It should be noted that the power of metagenomic technologies to identify all organisms present in a sample in an unbiased manner, can present the diagnostic laboratory with the challenge of identifying which of the many organisms detected in a sample might be the causative agent of the disease.

These results, and the recent experience gained in several diagnostic centres worldwide, indicate that the metagenomic detection of infectious agents is becoming a powerful, cultivation-independent and useful diagnostic tool, both in veterinary and human medicine (Granberg *et al.,* 2016; Wylezich *et al.,* 2018).

B. IMMUNODIAGNOSTIC TECHNIQUES

All immunoassays exploit the innate ability of antibodies to bind to an antigen (or epitope(s) within the antigen) with high specificity and affinity. Antibodies are often referred to as being monoclonal or polyclonal. Monoclonal antibodies (MAbs) are derived from a single B-lymphocyte, meaning that each antibody produced is identical to the next and will therefore bind only to a single specific epitope on an antigen. Polyclonal antibodies (PAbs) are essentially a collection of different MAbs as they are derived from a population of B-lymphocytes, so that each antibody is different to the next and may therefore bind specifically to different epitopes within the antigen.

MAbs are produced by immortalized B-lymphocyte clones called hybridomas, which are formed by the fusion of a myeloma cell with an individual B-lymphocyte taken from the spleen of an immunised animal. PAbs are produced in animals that have been exposed to a foreign antigen such as a pathogen or a vaccine and represent the full antibody response to that antigen. Thus, sera being tested will contain polyclonal antibodies whereas antibodies used as reagents in a test may be polyclonal or monoclonal.

Immunoassays are designed to detect pathogen-specific antigen or antibody in test samples, as indicators of active or prior infection. Antigens may be the pathogen itself, one or more of its subunits or proteins, a recombinant protein or a synthetic polypeptide. Antibodies will be those of host origin that the assay targets as a marker of infection and/or the reagent antibodies used to bind specific antibody or antigenic markers of disease. Reagent antibodies are commonly described according to their function. As examples, a primary antibody is used to bind directly to an antigen; a secondary antibody will bind to the primary antibody and be used to carry a label for detection; and a capture antibody will be used to immobilise an antigen.

Depending on the immunoassay format, antibody or antigen is first bound to a solid phase – typically the surface of micro-beads, a membrane, or the wells of an enzyme-linked immunosorbent assay (ELISA) plate. This provides a stationary point to which a specific target of interest binds or is captured. Thus, an immunoassay designed to detect an antibody response in a serum sample from an infected animal might use an antigen bound to the solid phase that is bound by pathogen-specific antibody in a test serum and this in turn is detected using a labelled secondary antibody. Where the target in a test sample is an antigen, an antibody on a solid phase is used to capture the antigen via a specific epitope and a second (often labelled) antibody directed towards an alternative epitope sandwiches the antigen and is used for detection. There are many variations on these assay formats but in all cases the specificity of antibodies for a given antigen forms the basis of the immunoassay. A wide range of useful reports is available in the literature, where various diagnostic systems were compared and recommendations were given for diagnostic laboratories concerning the specificity, sensitivity and usefulness of the various immunodiagnostic assays (Kittelberger *et al.*, 2011).

1. Enzyme-linked immunosorbent assay (ELISA)

ELISAs are the predominant immunodiagnostic tool used in veterinary diagnostic laboratories around the world. ELISAs exploit specific antigen-antibody interactions to detect specific antibodies to a pathogen, or a specific antigen of the pathogen. The conventional design of the ELISA has been extensively modified to meet a range of diagnostic requirements.

1.1. Principles of operation

The basic principle that underpins all ELISAs is the specific binding of antigen to antibody. Each type of ELISA exploits this interaction in a different way.

1.1.1. Indirect ELISA

Indirect ELISAs (I-ELISA) are used for the detection of antibodies in a serum sample to an antigen. In I-ELISA, the target antigen (whole or purified) is bound to the solid surface of the wells of an ELISA plate (solid phase). To perform the test, the following steps are performed:

i) Serum samples at an appropriate specified dilution are added to the wells. If specific antibodies against the coated antigen are present in the serum, they will bind to the antigen.

ii) The ELISA plates are then washed to remove any unbound antibodies.

iii) Antibodies raised against the immunoglobulins of the animal species being examined, are then added to the wells. These anti-species antibodies (or sometimes Protein A or G) are conjugated with an enzyme (usually a peroxidase).

iv) As all unbound antibodies from the serum sample are removed during the initial washing step, conjugated antibodies added at step (iii) can only bind to those antibodies already bound to the solid phase of the ELISA during step (i) (i.e. antibodies that are specific to the antigen of interest).

v) A second washing step is performed to remove any unbound conjugated antibodies.

vi) The enzyme substrate with a suitable chromogen, in substrate buffer, are then added. If any bound conjugated antibodies are present in the well (i.e. wells containing the antibodies of interest), the presence of the conjugated enzyme will cause the colour of the substrate buffer to change.

vii) This colour development is measured at a defined wavelength using a spectrophotometer. Higher quantities of antibodies in the sample result in increases in optical density.

I-ELISA is very sensitive for antibody detection, because reagents are added in excess (excess reagent is washed away) and this promotes rapid reactions and the amplification of signal due to the continual action of the enzyme that generates the colour change in the final step of the assay. The format can be made even more sensitive by adding more enzyme per molecule of conjugate. This may be done by biotinylating antibodies and then adding streptavidin-conjugated enzymes, or by using detection reagents that have scaffolds to which many more molecules of enzyme are attached, e.g. poly-HRP (horseradish peroxidase) streptavidin.

1.1.2. Antigen-capture ELISA

Antigen-capture ELISAs (Ag-ELISA) are used to detect the presence of pathogen-specific antigens in a sample and are useful for diagnosis prior to or during clinical disease.

The Ag-ELISA commonly follows a sandwich assay format. MAb or PAb specific to the antigens of interest are bound to the solid surface of the wells of an ELISA plate. The sample is then added to the well and any target antigens are captured by the bound antibodies. Captured antigens are subsequently detected through the addition of a second, enzyme-labelled MAb or PAb. The wells are then washed to remove any unbound conjugated antibodies before enzyme substrates and buffers are added. As for I-ELISAs, this will result in a detectable colour change in positive wells. Note that if the detecting antibody is not labelled, then an enzyme-conjugated antibody that targets the detecting antibody is used.

The desired characteristics of the capture antibodies are strong binding to the pathogen, recognition of a conserved epitope highly specific for the target agent, and the ability to attach to an ELISA plate without loss of reactivity. The detection antibody should recognise an epitope other than that recognised by the capture antibody that is bound to the ELISA plate. It may be difficult to identify MAbs of comprehensive intra-type reactivity and polyclonal antisera may be preferred to increase the likelihood of reaction against all antigenic variants.

Ag-ELISAs have been developed to detect many infectious agents, e.g. bovine viral diarrhoea virus (BVDV, see Mignon *et al.,* 1991), rinderpest and peste des petits ruminants virus (PPRV) (Libeau *et al.,* 1994). Related antigen-capture methods using antibody-coated immunomagnetic beads are now important and well accepted methods for detecting certain bacterial infections, including *Listeria, Salmonella* and *E. coli.* The principle of this technology relies on immunomagnetic separation, i.e. using small super-paramagnetic particles or beads coated with antibodies against bacterial surface antigens. The magnetic properties of the beads allow them to be retained whilst the beads are washed and moved to different buffers in a manner analogous to the methods described above for ELISA. Antigens such as intact bacteria or their soluble antigenic determinants can be detected after magnetic extraction from the test sample using a second antibody in a sandwich format. Antigen-capture assays using immunomagnetic beads can enhance the kinetics of the antigen–antibody reaction as the beads mix within the sample reducing the incubation time.

1.1.3. Blocking ELISA

Blocking ELISA (B-ELISA), used for detection of serum antibodies, shares some similarities with Ag-ELISA. Antibodies specific to the target antigen are bound to the solid phase of the ELISA plate. The antigen, prior to adding to the antibody-coated plate, is incubated with the samples. If the samples contain antibodies against that antigen, they will bind (block) to the antigen. When added to the wells, the blocked antigen will be unable to bind to the coating antibodies. Consequently, when the detecting antibody is added to the wells it will not recognise any bound antigen (no colour development). In contrast, if the sample is derived from a negative case, binding will occur and there will be colour development.

1.1.4. Competitive ELISA

Competitive ELISA (C-ELISA) is a variant of ELISA used to detect or quantify antibody or antigen using a competitive method. The principle of a competitive assay for the detection of antibodies is competition between antibodies that may be present in the test serum and the detecting antibody (which in this case binds directly to the antigen). Specific binding of the detecting antibody is detected using an appropriate anti-species conjugate or the antibody itself may be labelled. A reduction in the expected colour obtained is caused by binding of antibodies present in the test serum that are specific to the antigen, which therefore competes with the specific detecting antibody for antigen-binding sites. The C-ELISA offers significant advantages over I-ELISA; for example, samples from many species may be tested without the need for species-specific enzyme-labelled conjugates for each species under test, assays may be performed using less purified antigens, and may be faster to perform as they require less incubation time. In some cases, C-ELISAs may have lower analytical sensitivity than indirect ELISAs. Where the C-ELISA relies on competition between antibodies in the test serum and an MAb (detecting antibody) for binding to a single epitope on the antigen, false negatives may occur where the humoral response

of the host to the pathogen has targeted distinct epitopes on the antigen that differ from the MAb target epitope.

2. Immunoblotting

Immunoblotting is performed in diagnostic laboratories to identify and/or characterise infectious agents based on antigen specificity or using known antigens to detect a specific serological response. Immunoblotting combines the high resolution of gel electrophoresis with the specificity of immuno-detection and offers a means of identifying immunodominant proteins recognised by antibodies from infected animals or antibodies directed against the target agent. As an example of antigen detection, immunoblotting has been used on a large scale as a major screening method for bovine spongiform encephalopathy (BSE) and scrapie; it has been used on millions of brain stem samples in Europe and elsewhere for the detection of prion protein (Schaller *et al.,* 1999). It has now largely been replaced as a screening test by Ag-ELISA or lateral flow device-based methods but is still an important confirmatory test and is integral to the differentiation of transmissible spongiform encephalopathies strains into typical and atypical BSE and scrapie.

False-positive and false-negative results in other diagnostic assays can often be resolved by immunoblotting (Molina Caballero *et al.*,1993). Immunoblotting can also be used to determine the specificity of individual MAbs. Individual purified polypeptides (or recombinant proteins) may also be transferred to nitrocellulose or polyvinylidene difluoride membranes by immunoblotting to examine the reactivity of test sera to individual proteins. This characteristic profile of reactivity may be used to help distinguish between animals that have been vaccinated or infected, such as the enzyme-linked immunoelectrotransfer blot (EITB), a western blot for foot and mouth disease (FMD) that is widely used in South America (Bergmann *et al.,*1993).

The major factor affecting the success of an immunoblotting technique is the nature of the epitopes recognised by the antibodies. Most high-resolution gel techniques involve some form of denaturation of the antigen, which destroys conformational determinants and allows only the detection of linear or non-conformational epitopes. Most polyclonal antisera contain antibodies to both linear and conformational epitopes, but MAbs recognise single epitopes; thus, if they target conformational epitopes, they will not react with denatured protein.

3. Immunochromatography (lateral flow devices)

Immunochromatography provides a convenient method to detect antigens, antibodies (or any labelled molecule for which a ligand has been coated onto the chromatographic membrane, e.g. biotinylated LAMP products [see Section A.3 Isothermal amplification]) in several minutes without special apparatus (Fowler *et al.,* 2014; Hanon *et al.,* 2016; Waters *et al.,* 2014).

The sample is applied (usually with buffer) to one end of a membrane where there is a pad containing antibody- or antigen-conjugated microbeads (beads such as latex or colloidal gold). The antigen or antibody (dependent on format) in the sample forms an immunocomplex with the labelled microbeads. This complex moves along the membrane due to capillary action, until it makes contact with a corresponding antibody, antigen or ligand immobilised on the membrane, where it forms an immuno-complex and generates a coloured product that can be visualised by eye or read with a portable hand-held reader. Lateral flow devices (LFDs) show great potential for development into portable, pen-side diagnostic tests. Microbeads incorporating fluorophores can be used to produce LFDs with greater analytical sensitivity when applied with specific portable detectors (Liang *et al.,* 2017). Low cost, paper-based fluidics, may also have a greater role in the future, especially in the pen-side context (e.g. Yang *et al.,* 2018).

4. Reporter virus neutralisation tests

Reporter viruses may be derived from genetically manipulated viruses that are fully attenuated and that bear a marker gene encoding, for example, green fluorescent protein, or the *Renilla* or firefly luciferases. Alternatively, the envelope glycoproteins of the virus to be studied are expressed on a replication-deficient particle of a heterologous viral species that carries a marker gene, for example lyssaviral glycoproteins expressed on retroviral particles (viral pseudotypes). These innovative approaches, which reduce the bio-risk for the veterinary diagnostician and increase the sensitivity of virus neutralisation tests (VNT), have been developed for a range of viral pathogens, including rabies virus (Wright *et al*., 2008), influenza A virus (Carnell *et al.,* 2015), PPR, rinderpest and canine distemper viruses (Logan *et al.*, 2016a; 2016b), and Rift Valley fever virus (Schreur *et al.,* 2017). These technologies allow rapid quantification of neutralising antibodies as they obviate the need to wait for the development of plaques or other

cytopathic effects. They can potentially be multiplexed to develop VNT assays capable of detecting neutralising antibodies against distinct antigens (Molesti *et al.,* 2014).

5. Luciferase immunoprecipitation system

The luciferase immunoprecipitation system (LIPS) can also be used for pathogen-specific antibody detection. A recent application of this approach was described for the detection of PPRV-specific antibodies (Berguido *et al.,* 2016). In this assay, a reporter enzyme, *Renilla* luciferase (Ruc), is fused to an antigen of interest and expressed in mammalian cells. Subsequently, the Ruc-antigen fusion protein is recognised by antigen-specific antibodies, and antigen–antibody complexes are captured by protein A/G beads, which recognise the Fc region of the IgG antibody. The relative amount of antibody bound to the Ruc-tagged antigen is determined using a luminometer to measure the light produced when adding coelenterazine, the substrate for Ruc. This approach is species independent, provides a very specific and sensitive detection and requires very low volume of test serum.

6. Rapid homogeneous assays

Rapid homogeneous assays are those where the reagents are mixed together to form a homogeneous solution or suspension within which the antibody and antigen reactions rapidly take place. The assays require no further separations or washing and can be read without further liquid-handling steps. Examples of such assays include agglutination assays whereby a serum sample is mixed with a suspended particulate antigen and where the presence of serum antibody against the antigen causes the antigen to agglutinate (due to the multivalent nature of antibodies). More sophisticated methods include the fluorescence polarisation assay (FPA). This measures how the rate of spin of a molecule, for example an antigen, changes as it becomes larger due to the binding of antibody. An example of this approach is the *Brucella* FPA using fluorescein conjugated O-polysaccharide (Nielsen *et al.,*1996). A limitation of this approach is the need for highly purified antigen and an antigen that is small enough to spin rapidly when not bound to antibody. Two readings are required, one to measure the background fluorescence of the sample and the other to measure the fluorescence of the reaction after antigen addition. Other methods that are used in the pharmaceutical industry for high-throughput compound screening include competitive methods where complementary ligands, analogous to antigens and antibodies, are labelled with tags that measurably interact with each other on a proximity basis, with signals increasing as they get closer (indicating binding has taken place). The introduction of competing reagents, for example unlabelled serum antibody, impedes this reaction leading to the consequent measurable reduction of signal (McGiven *et al*., 2009). When compared with other diagnostic methods, FPA assays exhibited high sensitivity, e.g. for the diagnosis of bovine brucellosis (Praud *et al*., 2016).

C. BIOTECHNOLOGY APPROACHES FOR THE PRODUCTION OF DIAGNOSTIC REAGENTS

1. Recombinant DNA technology to produce diagnostic reagents

These technologies are now also being used to produce protein-conjugated polysaccharides (Cuccui & Wren, 2015) as the genetic code for the protein carrier, the proteins required for the synthesis of the glycans and the code for the proteins required to conjugate the glycans to the carrier can all be inserted into host bacterial cells (such as *E. coli*). Although directed primarily towards the generation of vaccines, such recombinant glycoproteins can also be used for serodiagnosis, for example the detection of anti-*Brucella* antibodies in cattle and pigs. (Ciocchini *et al*., 2014; Cortina *et al.,* 2016). These antigens offer the traditional advantages of recombinant proteins, such as purity of product and avoiding the need to culture the native organism (in this case a highly infectious zoonotic agent) but also enable the production of highly important non-protein diagnostic antigens such as glycans in a form (conjugated) that facilitates their use as diagnostics and vaccines.

Recombinant DNA technology enables the production of antigens for various diagnostic applications such as ELISA, agglutination, haemagglutination inhibition (HI) tests, agar gel immunodiffusion (AGID) tests, complement fixation tests (CFT), as well as microarray and bead-based technologies.

For antibody production, recombinant antibodies are used as an alternative to the traditional hybridoma-based technology in generating high quality antibodies. Phage display, yeast display and ribosomal display are some of the approaches used to produce antibodies in prokaryotic, eukaryotic and *in-vitro* systems, respectively (Sutandy *et al.,* 2013).

2. Synthetic antigen biology

By circumventing biological systems completely, the recreation of antigen structure via synthesis also offers many advantages over native antigen extraction. This includes high levels of purity and reproducibility, simple scale up capability and bespoke antigen design.

An upcoming trend in the production of antigens for use in assays is the development of synthetic peptide antigens. This allows antigens to be tested as diagnostic reagents based on the gene sequence; expression of the whole protein is unnecessary, thus shortening the process. Glycosylated peptides can also be synthesised (Bednarska *et al.,* 2017). The cost and benefits are such that recombinant production systems still dominate for the production of large proteins. However, for non-protein antigens where the underlying genetic basis for production is unclear and thus recombinant production is not possible, synthesis is a very viable and successful option for diagnostic antigen production. This has been shown for brucellosis where the epitopes that exist in the native structure of the O-polysaccharide from *B. abortus* S99 and *B. melitensis* 16M have been synthesised and the synthetic antigens have been shown to be highly effective for serodiagnosis (Guiard *et al.,* 2013; McGiven *et al.,* 2015).

Synthetic DNA can be generated from sequence data and then used with recombinant technology to generate proteins and even complete viruses for the rapid production of vaccines, such as influenza (Dormitzer *et al.,* 2013).

D. TECHNOLOGIES APPLICABLE TO DETECTION AND ANALYSIS OF ANTIGENS, ANTIBODIES AND NUCLEIC ACIDS

1. Microarray technologies

A microarray is a two-dimensional arrangement of specific biological probes (e.g. DNA, proteins, peptides, glycans) immobilised on solid substrates such as a glass slide, polymer-coated glass, plastics, nitrocellulose, etc. (Barbulovic-Nad *et al.,* 2006). A microarray provides high multiplexing capability, i.e. hundreds or thousands of detections can be performed at a time. Microarray chips can be created to identify the cause of syndromic disease, for example, a chip that targets panels of encephalitic pathogens or to target species-related diseases, e.g. swine disease chips. Similarly, chips of very high specificity may be designed to detect multiple targets for a given pathogen. Using array-based approaches can present some challenges in handling and analysis of the very large data sets that are generated. Instrumentation and consumables may also be cost-prohibitive for some laboratories.

1.1. DNA microarrays

DNA microarrays exploit the ability of complementary strands of nucleic acids to hybridise, and involves the following steps:

i) Nucleic acids isolated from biological sources are amplified and labelled with a fluorescent dye.

ii) The single-stranded, labelled DNA products are then added to the surface of the DNA microarray. This results in hybridisation of the sample nucleic acids with the complementary biological probes in the microarray, creating a labelled double-stranded molecular structure on the surface of the array.

iii) The microarray is then rinsed to remove non-specifically bound target molecules and evaluated using a laser scanner.

DNA microarray technology is a useful tool with a variety of diagnostic applications. This technology offers the possibility of detecting and identifying pathogens of veterinary and public health importance in the target sample (Ojha & Kostrynska, 2008). It can also be used for epidemiological investigations and genotyping of pathogens. With technological advances, DNA microarrays have also progressed toward the discovery of new emerging pathogens. For instance, an array consisting of highly conserved 70-mer probes from all sequenced reference viral genomes was used to demonstrate that a coronavirus was responsible for severe acute respiratory syndrome (SARS).

DNA microarrays are particularly useful for multiplex assays and have been used to detect and determine all possible HA and NA subtypes of avian influenza virus (Belák *et al.,* 2009). The most recent generation

of microarrays enables DNA sequence analysis, often providing complete genome sequences in a single experiment.

1.2. Protein microarrays

Protein microarrays are produced similarly to DNA arrays by immobilising proteins at high density on a solid surface (Sutandy *et al.,* 2013). The arrays contain specific probing molecules such as antigens or antibodies that can be recognised via fluorescent labels or detected by mass spectrometry (MS) (SELDI-TOF [surface-enhanced laser desorption/ionization-time of flight] or MALDI-TOF [matrix-assisted laser desorption/ionisation-time of flight]) (Sutandy *et al.,* 2013; Yu *et al*., 2006). The principle of the reaction between an immobilised capture molecule and a protein target analyte present in the sample relies on antibody/antigen recognition or protein/protein interaction. Protein arrays are used for antigen or antibody detection in blood samples, the discovery of disease biomarkers and the discovery of the mechanism of pathogenesis and immune response to a pathogen by different host. For example, a protein microarray containing 1406 predicted *Brucella melitensis* proteins was used to screen sera from experimentally infected goats and naturally infected humans and to demonstrate the differences in the immune response in goat and humans following *B. melitensis* infection (Liang *et al*., 2010). In addition, protein microarrays can be used for detection of antibodies directed against specific pathogens and monitoring the changes in cellular protein expression.

Surface-enhanced laser desorption/ionisation-time of flight mass spectrometry

Technological advances have enabled the microarray platform to achieve sufficient standardisation and method validation as well as efficient probe printing, liquid handling and signal visualisation. Some major challenges from using protein microarrays in routine diagnostics are the need for highly specific antibodies to prevent false-positive results and the need to produce large numbers of antibodies in a high throughput fashion (Sutandy *et al*., 2013).

2. Bead-based arrays

Bead-based arrays and cytometric bead arrays are variants of probe-based assays that provide the opportunities for multianalyte profiling targeting nucleic acids, antigens or antibodies (Christopher-Hennings *et al.,* 2013). In the technique, pathogen-specific nucleic acid, antigen or antibody is covalently linked to microsphere beads. An advantage of the technology is its multiplex capability that results from the beads themselves having a fluorescent signature (such that each bead can carry a specific probe). Bead-based assays are increasingly being used in multiple pathogen detection tests to look for the nucleic acids of several pathogens (Boyd *et al.,* 2015) or antibodies to different pathogens in a single sample (Sánchez-Matamoros *et al.,* 2016). If there is a requirement for testing many serum samples for a panel of diseases (e.g. several different antigens), including the possibility of multiple antigens per disease, then multiplex bead-based arrays offer an efficient means for this. Recent examples exploiting the multiplex capability of this technology are the application to genotyping of African swine fever virus (LeBlanc *et al*., 2013) and DIVA (differentiation between vaccinated and infected animals) test for FMD (Chen *et al.,* 2016).

3. Biosensors

Biosensors use an immobilised biosensing element (DNA, RNA, antigen/antibodies or glycans), also known as a bioreceptor, to recognise a characteristic biomarker of the pathogen. The resulting biochemical interaction between the biomarker and the bioreceptor is converted into a measurable signal by the transductor and displayed (Vidic *et al.,* 2017). Biosensing is based on optical electrochemical and mass-based transduction methods (Alahi & Mukhopadhyay, 2017). This approach has been used for influenza A antigen detection (Hideshima *et al.,* 2013; Lee *et al.,* 2013), and the detection of antibodies to *Mycoplasma bovis* (Fu *et al.,* 2014).

4. Mass spectrometry

Mass spectrometry (MS) can detect biomarkers present in a sample, based on their mass. Infection with a microorganism can be detected by comparing the profile of biomarkers present in a sample to a database of samples known to be positive for the organism of interest. This is the premise of diagnostic modalities including MALDI-TOF MS. This approach was used for *Staphylococcus intermedius* and for the direct identification of bacteria in blood cultures (Guardabassi *et al.,* 2017). Some approaches have also been developed to identify protein biomarkers as a means of virus identification. MALDI-TOF MS can also be used for sequencing short DNA

fragments, as an alternative to conventional sequencing when high throughput automated screening for mutations is needed.

One electrospray ionisation (ESI)-based platform, combining the accuracy and the sensitivity of MLST with the speed and throughput of MS, has been developed for rapid identification of pathogens (Kailasa *et al*., 2019). Similarly, several applications using the MALDI-TOF MS are available for genotyping or single nucleotide polymorphisms (SNP) typing and resequencing.

4.1. Proteomics

MS is also used in proteomics. The proteome is the total complement of proteins expressed within a cell, a tissue or an organism. Proteomics is the study of proteins, including their expression level, post-translational modification and interaction with other proteins. As not all proteins are expressed at all times, but are dependent on physiological and environmental factors, proteomics can provide an excellent overall view of disease processes at the protein level. For example, definitive diagnosis of chronic hepatitis B virus (HBV) infection still relies on liver biopsy, but proteomic analysis of serum samples shows that the expression of at least seven serum proteins is changed significantly in chronic HBV patients. Similarly, the ante-mortem differential diagnosis of Creutzfeldt-Jakob disease (CJD) may be aided by proteomics as preliminary data show that seven proteins in cerebro-spinal fluid (CSF) are differentially expressed between patients with variant or sporadic CJD (Choe *et al.,* 2002). Within the veterinary field, proteomic studies have been developed for a variety of applications for animal and zoonotic diseases (Katsafadou *et al*., 2015; Patramool *et al*., 2012; Torre-Escudero *et al*., 2017).

5. *In-situ* detection of antigens and nucleic acids

Different techniques are available for the direct detection of pathogen proteins, antigens or nucleic acids in animal tissues or body fluids. In some cases, the same technology can be applied to the detection of antibodies in serum.

5.1. Immunofluorescence

The fluorescent antibody test (FAT) is used for the detection of pathogens in animal tissues or fluids, using specific antibodies against the targeted antigens. As the method is based on direct binding of the labelled antibody to the antigens of the infectious agent present in the sample, it is commonly called direct immunofluorescence. The method is commonly used in diagnostic laboratories, e.g. for the detection of the rabies virus in the brains of dead animals and classical swine fever virus in tissues of suspected pigs.

A modification of the FAT can be used for the detection of specific antibodies, produced by the immune system against various pathogens during infections. Essentially, the modification is in the use of secondary antibody specific for the antibodies of the species examined. This procedure is commonly referred to as indirect immunofluorescence. The method is commonly used in diagnostic laboratories for the detection of antibodies raised against a wide range of pathogens, e.g., African swine fever virus (Cubillos *et al*., 2013), *Coxiella bernetii*, causative bacteria of Q fever (Roest *et al.,* 2013) and many other infectious agents in veterinary medicine.

Another modification of direct immunofluorescence uses an unlabelled primary antibody derived from a specific species to recognise pathogen-specific antigen, and this antibody is subsequently bound by a secondary anti-species immunoglobulin antibody that is conjugated to a fluorophore. This procedure is also commonly referred to as indirect immunofluorescence.

5.2. Immunohistochemistry

Immunohistochemistry involves the *in-situ* detection of antigens in fixed tissues using labelled antibodies. As an adjunct to the isolation of causative organisms from tissue, immunohistochemistry has become a standard tool to identify pathogens in tissue, and for confirmation of the results obtained using other diagnostic technologies. Immunohistochemistry is commonly used for the detection of abnormal prion protein (PrP^{Sc}) in brain tissue to confirm scrapie, BSE and other transmissible spongiform encephalopathies, and is more sensitive than standard histopathological examination (Thorgeirsdottir *et al*., 2002). In recent years, diagnostic tests based on immunohistochemistry have been successfully

developed and applied to rabies virus detection in clinical specimens (Rahmadane *et al*., 2017). As the number of antibodies to defined antigens increases, the use of immunohistochemistry for the identification of organisms and other specific markers for autoimmune diseases and neoplasia is increasing.

Due to the use of fixatives to prepare samples, IHC offers several advantages over pathogen isolation methods, including:

i) convenience of sample submission;

ii) safe handling of zoonotic pathogens;

iii) retrospective studies of stored specimens;

iv) rapidity; and

v) the detection of nonviable organisms (Haines & Clark, 1991).

As formalin fixation can denature the antigenic epitopes (i.e. the three-dimensional structure recognised by some antibodies) the limiting step in the application of immunohistochemistry is to identify an appropriate antibody/antigen combination that will bind antigen in formalin-fixed tissues. This may be overcome by using frozen sections or employing antigen retrieval techniques (e.g. proteolytic enzyme digestion, microwaving) before immunostaining.

5.3. *In-situ* hybridisation (ISH)

This technology exploits two natural phenomena: the unique genetic code or signature a pathogen contains in its genome and the ability of single-stranded nucleic acid sequences (DNA or RNA) to anneal or bind with complementary single-stranded nucleic acid sequences to form double-stranded hybrids. In its simplest form, *in-situ* hybridisation (ISH) uses single-stranded DNA or RNA probes that are produced synthetically and are designed to complement a short specific region of a pathogen's genome. Probes are coupled to labels that are readily detectable using microscopy and may include fluorescent dyes, fluorescent nanoparticles or enzymes that produce a chromogenic product when treated with substrate.

Recent commercial supply of ISH reagents has made the technique more accessible and is likely to see greater uptake by diagnostic laboratories in the future. A noteworthy application of ISH is in the rapid development of tests for detection of newly emerging pathogens. As soon as sequence data generated during identification of the novel pathogen by high throughput sequencing (see Section D.vi) becomes available, probes may be designed and assays developed. In contrast, antibody/antigen-based reagents required for the development of immunoassays take considerably longer to generate.

E. IMPLICATIONS OF THE NEW TECHNOLOGIES

There are several trends in diagnostic technology development, e.g. multiplexing of assays, evaluation of complexity in the biology of infection, that will have an impact on the way disease diagnoses will be approached in the future, affecting the laboratory environment, data analysis and disease control:

i) The global development of chip technologies has led to a strong trend towards miniaturisation of the test format in both molecular and protein detection assays. The test formats range from several millimetres to several centimetres. In parallel, a wide range of simple diagnostic tools, such as lateral flow assay devices were developed for the improved, on site (point-of care) diagnosis of many diseases. These changes enable on-site testing, facilitating the rapid and affordable diagnosis of the targeted infectious diseases. Appropriate infrastructure and preparedness must be an integral component of technology update, including training in the use and interpretation of such methods.

ii) Simplification of technologies, development of smaller, more simple and affordable devices is also seen in other fields of veterinary diagnostic microbiology, for example in rapid and high throughput sequencing technologies. The development of simple devices and improved sample preparation technologies will facilitate the direct sequence analysis of clinical samples not only in central institutes, but also on site in the field or in simply equipped field laboratories. During this work it will be very important to focus not only on the

rapid technical development of sequencing equipment, but in parallel, to strengthen the knowledge of bioinformatics and to maintain general knowledge in veterinary medicine and epidemiology.

iii) The development of alternative sources of signal generation/amplification, replacing light with mass measurement, piezoelectric effect or concentration of the ligand will lead to the development of a whole new platform of technologies.

iv) Although the development of new technologies can often mean faster results and improved capability, consideration should always be paid to the actual value and the role of the confirmatory test in diagnosis and of the modes of reaction of appropriate Competent Authorities. In this context, the expertise present in laboratories remains as important as ever in explaining the significance and limitations of diagnostic results.

v) Increasingly, traditional, well understood methods that use low cost equipment are being replaced with more complex methods requiring increased investment. These newer methods often require higher diversity of expertise in laboratory personnel and are associated with increased turnover in platforms as relatively recent systems become redundant. This has implications for laboratory resourcing and the structure of laboratory networks within and between countries as laboratories become more specialised.

vi) In-depth analysis of pathogens, for example through high throughput sequencing, is increasingly becoming an expected part of reference laboratory operations. As the diagnostic platforms are continuously changing in the ways described above, several components of the disease control chain will be affected. Appropriate communication technologies/information systems will need to be developed to systematically collect, store and analyse the large datasets produced by the new technologies in a relatively short time. For example, there is likely to be an increasing trend towards real-time inputs of results via mobile platforms. These trends will require ongoing development of bioinformatics, information technology and data-handling systems.

vii) Methods with high levels of analytical sensitivity and specificity are increasingly available to laboratories and are enabling the rapid identification and response to infectious veterinary disease, improving the effectiveness of control and eradication methods. These developments provide new opportunities for the identification and characterisation of the infectious agents and for the improved control of infectious diseases in veterinary medicine.

viii) Novel, biotechnology-based methodologies open a wide range of new possibilities and challenges in diagnostic microbiology. Thus, it is strongly advised to consider powerful new methods and to introduce these new technologies at our diagnostic laboratories. However, it is important to determine what is the exact diagnostic capacity and value of the new technologies and to what extent can these methods replace the classical diagnostic approaches. In general, the safest way is to maintain a multidisciplinary complex of diagnostic approaches and capacities at our laboratories, providing a practical combination of powerful new and classical technologies and a properly balanced knowledge of veterinary diagnostic medicine, infection biology and epidemiology.

CHAPTER 2.1.3.

MANAGING BIORISK: EXAMPLES OF ALIGNING RISK MANAGEMENT STRATEGIES WITH ASSESSED BIORISKS

A. INTRODUCTION

Chapter 1.1.4 Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities *describes the use of biorisk analysis for effectively identifying and managing laboratory biosafety and biosecurity risks for individual veterinary laboratories and animal facilities based on their unique facility, infrastructure, and the surrounding environment in which the biological agent or toxin is to be handled, including relevant national policies and legislation. The process of biorisk analysis includes biohazard identification, biorisk assessment, biorisk management, and biorisk communication.*

This Guideline provides, in a table format, two working ***examples*** *of the risk assessment component of the process. The risk assessments include review of laboratory control measures that a fictional veterinary laboratory evaluated in order to protect laboratory workers from inadvertent exposures and infection, and also importantly to protect as appropriate the local and regional animal populations, human populations, and environment from accidental or intentional release and spread of a biological agent or toxin from their laboratory or animal facility. As such, the risk analysis includes consideration of the likelihood of an event occurring and the consequences of such an event.*

The first example uses Bacillus anthracis*, a zoonotic agent, as an example of a biosafety risk managed by veterinary laboratories that is also considered a biosecurity risk based on its potential as a biothreat agent. The second example uses foot and mouth disease (FMD) virus as an example of a veterinary pathogen of variable economic significance depending on the endemic disease status and the location of the laboratory in relation to geopolitical borders. The FMD example represents an assessment completed by a laboratory located in an FMD-endemic area, and importantly notes in the assessment where laboratory control measures will be re-evaluated and modified as FMDV is eradicated in the specific region. Disease control and eradication programmes increase the economic impact of the disease and associated biorisks of handling the agent in the laboratory.*

NOTE: *It must be stressed that the two examples provided here are just that – examples invented for the purpose of showing what an actual laboratory may need to evaluate or consider as part of its biorisk assessment. The text in bold in the tables indicates matters that should be included in any agent-specific risk assessment. The text not in bold is fictitious data included to help demonstrate the process. It is equally important to note that the examples are short, concise summaries of biorisk analyses. Dependent on the complexity of the specific-agent, the laboratory facility, the proposed laboratory procedures, and the regulatory environment, actual biorisk analyses may vary from a similar short summery to a multiple-page dossier.*

Example Risk Analysis 1: Anthrax

Hazard: *Bacillus anthracis*

Location: Country where anthrax is not usually considered endemic but disease freedom not claimed – laboratory located in site where there are no domestic animals and no habitations (20 km around the facility).

Pathogen and disease: Anthrax is an acute bacterial disease primarily of herbivores and is transmissible to humans. It is caused by *B. anthracis*, a Gram-positive spore-forming rod-shaped bacterium.

Animals become infected by ingesting spores or possibly by being bitten by flies that have fed on an infected animal or carcass. Infected animals are usually found dead as death can occur within 24 hours. A careful post-mortem examination of recently dead animals may show any number of lesions, none of which is pathognomonic or entirely consistent. To avoid environmental contamination, post-mortem examinations conducted in the field (outside of laboratory containment) of carcasses of animals suspected to have died of anthrax is discouraged. Lesions most commonly seen are those of a generalised septicaemia often accompanied by an enlarged spleen having a 'blackberry jam' consistency and poorly clotted blood. Haemorrhage from the nose, mouth, vagina and/or anus at death is not a common sign.

More than 95% of human anthrax cases take the cutaneous form and result from handling infected carcasses or hides, hair, meat or bones from such carcasses. *Bacillus anthracis* is not invasive and requires a lesion to infect. Protection for veterinarians and other animal handlers involves wearing gloves, and other protective clothing when handling specimens from suspected anthrax carcasses and never rubbing the face or eyes. The risk of gastrointestinal anthrax may arise if individuals eat meat from animals infected with anthrax.

NOTE: The Table that follows is an example. The cells have been filled in in response to an imaginary scenario. The data are fictitious and included to help demonstrate the process. The requirements in the hypothetical examples are based on the country's standards and guidelines, as would be used for an actual biorisk analysis.

RISK ASSESSMENT (Likelihood and Severity)	RISK MANAGEMENT Administrative Controls	RISK MANAGEMENT Operational Controls	RISK MANAGEMENT Engineering Controls	RISK MANAGEMENT Personal Protective Equipment
Health Risk **Humans** – YES, treatment available. **Animals** – YES, treatment not usually attempted or recommended, case fatality rate high, herd morbidity variable. **Transmissible by** contact with body fluids of infected animals or carcasses, excretions of infected animals, or contaminated environment.	**Requirements:** **1. Communication plan**: reportable disease list and reporting requirements for both animal and public health authorities. **2. Qualified/suitable staff**: training and competency requirements for work with infectious diseases in place and current for all laboratory staff. **3. Health and safety programme**: prophylaxis and treatment for anthrax exposures reviewed. **4. Accident/incident reporting programme** **5. Emergency response plan**: actions including notification list for accidental exposure, spill/ contamination in lab, release from lab, and theft of agent. **6. Agent inventory management programme** **7. Waste management policy** **8. Security programme**: laboratory biosecurity for preventing unauthorised access to *B. anthracis*.	**Requirements:** **1.** Standard operating procedures (SOPs) and training materials comprehensively covering **laboratory safety and laboratory biosecurity** comprehensively that address the biorisks posed by the handling and storage of suspect diagnostic case materials and *B. anthracis* cultures. Good Laboratory Practices included in all working SOPs. **2. Disinfection/decontamination** SOPs are written for disinfecting/decontaminating necropsy and laboratory areas and equipment, for carcasses and tissues, for packaging and shipping materials, and for laboratory wastes. **3. Transport** SOPs, regulatory approvals, and certifications for packaging and shipping to the reference laboratory are current. Sample (specimen) containment SOPs are in place for movement within the laboratory facility. **4. Response plan** drill/exercise specific to *B. anthracis* identification from clinical materials and to associated laboratory responses, including incident response to spills and release from the laboratory. **5. Accident/incident reporting** and response SOPs and forms, audit schedule for reviewing accident reporting. **6. Audit and review schedule** for *B. anthracis* biorisk assessment and management	**Requirements:** **1. Biocontainment** addresses prevention of accidental and/or deliberate release of infectious material. **2. Separation of incompatible activities** **3. Equipment maintenance, calibration, certification** current **4. Facility security**	**Requirements:** **Personal protective equipment** (PPE): respiratory protection and dedicated laboratory clothing.
In the Laboratory **Necropsy:** body fluids released, environment contaminated, high risk of human	**Assessment findings:** 1. Reporting plan for *Bacillus anthracis* and contact list (names	**Assessment findings:** 1. Good microbiology practices followed by all lab staff; review included in	**Assessment findings:** 1. Biosafety cabinets located in sample receiving area and microbiology area. Centrifuge equipped with closed carriers	**Assessment findings:** 1. Respiratory protection available on-site for receiving, necropsy, microbiology staff.

RISK ASSESSMENT (Likelihood and Severity)	RISK MANAGEMENT Administrative Controls	RISK MANAGEMENT Operational Controls	RISK MANAGEMENT Engineering Controls	RISK MANAGEMENT Personal Protective Equipment
exposure by contact with body fluids and by inhalation. **Handling of specimens:** unknowns via diagnostic submissions including tissues, carcasses. (High risk for exposure to spores), swabs of blood, other body fluids or swabs taken from incisions in tissues or organs can be source of exposure (low exposure risk) **Volumes and concentrations:** Anticipate two diagnostic cases per year (moderate risk). Amplification with short and long-term storage on solid media, <1 mg agent (moderate risk) **Diagnostic test methods:** Identification and characterisation of the agent: Culture, immunological detection, characterisation and differentiation from vaccine strain by polymerase chain reaction (PCR). **Research:** No experimental work to be conducted **Bacterial isolate archives:** Short and long term storage of isolates. (High risk for intentional misuse – see Security risks.)	and numbers) is current. Includes public health, animal health. 2. Training and competency in good microbiology practices current for all staff. Anthrax-specific training for clinical disease recognition and handling competency documented for pathology staff. Anthrax-specific training for handling of high risk specimens for receiving and testing lab staff. 3 and 4. Employee health and safety programme in place. - All employees enrolled in the health and safety programme, trained in accident reporting policy and procedures. - Policy and procedure for providing health information and health surveillance related to Anthrax exposure for non-employee trainees and students present in the laboratory is in place. - Anthrax prophylaxis and treatment options reviewed with occupational health officer: decision made not to vaccinate lab staff. 5. Response plan addresses accidental and intentional release of *Bacillus anthracis*. All employees trained on plan. 6. Agent inventory management plan addresses access, secure storage, transfer, and destruction. Mandates annual audit and reconciliation of inventory records. Laboratory storage and archive system and procedures comply with	annual audit of laboratory practices to insure compliance. Current SOPs are in place for receiving, processing, testing, storage, and disposal of *B. anthracis* suspect case materials. Microbiology culture SOP includes steps to minimise potential for spore formation and subsequent exposure of staff to spores (reduction in anthrax inhalation biorisk) 2. General disinfection and decontamination protocols in place for all laboratory areas. Gap: The general disinfection/decontamination plan for the laboratory does not include specific references for disinfectants, concentrations, and contact times for *B. anthracis.* SOPs and training materials for recognition, handling, and destruction of high risk *B. anthracis* specimens in place. 3. Certification current for staff member responsible for packaging and shipping to reference laboratory. SOP for movement of *B. anthracis* within the laboratory includes requirement for transport in a secondary leak-proof non-breakable container marked with a biohazard label. 4. Emergency response plan was exercised within the prior 12 months; exercise specific to anthrax identified a gap: *Actions needed: Restrict potential for inadvertent contamination from necropsy area by (1) restricting visitors, (2) developing a policy for visitors (no street clothing or shoes in necropsy area), (3) review SOP with staff on rendering of carcasses from necropsy area to address*	(aerosol containment). Additional documents needed: Effluent treatment verification records, certifications for directional airflow. 2. Clerical areas separate from testing areas. Dedicated secure freezer used for agent inventory. 3. Biosafety cabinets in receiving and microbiology sections have certification of correct operation (air-flow) verified annually per pre-existing preventive maintenance schedule. 4. Doors to testing areas can be locked. Entry to building controlled by key-card access and alarmed off-hours. Inventory storage location is secured by lock and key, with key access available only to authorised personnel. The necropsy area used for short term storage of the carcass prior to incineration and disposal is secure and signage is posted to prevent unauthorised access.	Dedicated coveralls and boots used in necropsy area. Laboratory coats, gloves used for all specimen handling. SOPs for putting on and removing PPE available and systematically followed, PPE regularly collected and laundered in appropriate facility *Gap: Insure availability of coveralls and boots on-site for authorised visitors (students/trainees) to necropsy area.*

RISK ASSESSMENT (Likelihood and Severity)	RISK MANAGEMENT Administrative Controls	RISK MANAGEMENT Operational Controls	RISK MANAGEMENT Engineering Controls	RISK MANAGEMENT Personal Protective Equipment
	relevant national regulations for *B. anthracis.* 7. Waste management policy addresses carcasses, tissues, and all laboratory wastes containing potentially infectious material. All anthrax-suspect material to be diverted from laboratory rendering. 8. Laboratory biosecurity includes restricted access to testing areas. Biohazard signage available to post at entrance doors. Key-controlled access to incubator and freezer used for storage of *B. anthracis* cultures. *Gap: Laboratory policy needed to define the boundaries regarding types of research to be allowed, and* B. anthracis *to be included in risk profiles of organisms with which research will not be conducted.*	*holding, decontaminating or destroying potentially contaminated hides/ carcasses, and (4) develop a laboratory labelling system to clearly identify high-risk and/or potential zoonotic agent containing carcasses or specimens during short and long-term storage.* 5. Accident/incident reporting protocols cover *B. anthracis*. Laboratory director and safety officer review of all accident reports. Accident/Incident reporting is a component of the laboratory quality system and continual improvement plan and is audited annually. 6. Audit of *B. anthracis* control measures is scheduled for 30 days following first case presented. Review of risk assessment and management plan is scheduled to be completed annually and immediately after any significant change to the laboratory facility or management.		
ECONOMIC RISKS				
Endemic in region: 1. Sporadic cases possible.				
Trade barrier: A possibility to be managed. (High risk for restriction against movement of wool and hides.)	*In progress: Veterinary Authority advised that* B. anthracis *may be worked with in the laboratory, currently reviewing economic risks to region, working with trade partners to assess impact on trade related to laboratory handling and storing* B. anthracis.			
ENVIRONMENTAL RISKS				
Stabile in environment: YES. (High risk for soil contamination; spores stabile for years.)		SOP on handling of anthrax suspect carcasses, includes movement from necropsy area to holding area, decontamination and destruction of potentially	Microbiology laboratory liquid waste and solid waste inactivated before release.	

RISK ASSESSMENT (Likelihood and Severity)	RISK MANAGEMENT Administrative Controls	RISK MANAGEMENT Operational Controls	RISK MANAGEMENT Engineering Controls	RISK MANAGEMENT Personal Protective Equipment
		contaminated hides/carcasses to insure no release to landfill or rendering facilities.		
SECURITY RISKS				
Short- and long-term storage of isolates. (High risk for intentional misuse.)	Security policy and procedures in place: laboratory security programme includes visitor restrictions. Biothreat: Authority/agency has reviewed laboratory security policy, chain of custody and investigative protocol required if laboratory becomes involved in diagnosis/investigation of intentional Anthrax exposure incident.	Access to inventory records restricted by password protection. Inventory reconciled with inventory records annually, and immediately if unauthorised access is suspected.	Inventory access controlled by lock on storage freezers, and alarm to inventory area.	

Risk communication

Notification to appropriate public health authority and animal health authority

The laboratory is planning to begin diagnostic testing for *Bacillus anthracis* (anthrax) in order to support the detection and diagnosis of a naturally occurring or intentional introduction of the agent affecting local livestock species. The laboratory has completed a laboratory biorisk assessment and has in place appropriate control measures to prevent accidental exposures and release of the agent from the laboratory. The designated laboratory contact person is _____.

Actions to be completed:

1. In consultation with the national animal health authority, identify responsible person(s) and develop a message to be activated in the event of a positive anthrax diagnosis, including a press release, contact lists and a questions and answers document.

2. In consultation with the national animal health authority and/or public health authority as appropriate, identify responsible person(s) and develop a communication message to be activated in the event of a laboratory spill or accident, or accidental human infection with *B. anthracis*.

3. In consultation with the national animal health authority, public health authority and/or security agency as appropriate, identify responsible person(s) and develop a communication message to be activated in the event of a real or apparent deliberate release of the anthrax organism.

Verification, corrective actions, and continuous improvement

Action to be completed: Schedule and conduct internal audits of policy and procedures relating to the handling of organisms that constitute risks such as posed by *B. anthracis*. Exercise (audit) the pathway of activities and actions that would be followed in the laboratory should a potential anthrax disease submission be received. Perform an additional review of the biorisk assessment and control measures should changes be made to the facilities, management practices, or technical procedures associated with the laboratory handling and storage of the anthrax organism.

Example Risk Analysis 2: Foot and mouth disease

Hazard: Foot and mouth disease

Location: Country is FMD-endemic, disease control and eradication efforts are in initial phases. Laboratory located at a fenced site; no susceptible animals within 3 km of the facility.

Pathogen and disease: FMD is a highly contagious viral disease of cattle and swine. It also affects sheep, goats, deer, and other cloven-hooved ruminants. The disease is caused by a non-enveloped virus of the genus *Aphthovirus*, family *Picornaviridae*. There are seven serotypes of FMD virus (FMDV), namely O, A, C, SAT 1, SAT 2, SAT 3, and Asia 1 with various subtypes. Infection with any one serotype does not confer immunity against another. Within serotypes, many strains can be identified by biochemical and immunological tests.

The transmission of FMDV occurs either by direct contact between infected and susceptible animals, by direct contact of susceptible animals with contaminated material or objects (hands, clothing etc.) or by consumption of untreated contaminated meat products (primarily by pigs). Furthermore, inhalation of infectious aerosols is known. Humans can be carrier of FMDV in their respiratory tract for up to 48 hours.

FMD is characterised by fever and blister-like lesions followed by erosions on the tongue and lips, in the mouth, on the teats, and between the hooves. Most affected animals recover, but the disease leaves them debilitated. The severity of clinical signs varies with the strain of virus, exposure dose, age and breed of animal, host species, and degree of host immunity. Signs can range from mild or inapparent to severe. Morbidity may approach 100%. Mortality in general is low in adult animals (1–5%) but higher in young calves, lambs and piglets (20% or higher). Recovery in uncomplicated cases is usually about 2 weeks.

NOTE: The Table that follows is an example. The cells have been filled in in response to an imaginary scenario. The data are fictitious included to help demonstrate the process. The requirements in the hypothetical examples are based on the country's standards and guidelines, as would be used for an actual risk assessment.

RISK ASSESSMENT (Likelihood and Severity)	RISK MANAGEMENT Administrative Controls	RISK MANAGEMENT Operational Controls	RISK MANAGEMENT Engineering Controls	RISK MANAGEMENT Personal Protective Equipment
Health risk: **Humans** – NO **Animals** – YES (domestic and wild hoofstock) **Transmissible by** direct contact with infected animals, their excretions, or contaminated environment; consumption of contaminated meat; aerosol transmission over distances is documented (references on file).	**Requirements:** **1. Communication plan**: reportable disease list and reporting requirements for animal health authority. **2. Qualified/suitable staff**: training and competency requirements for work with infectious diseases in place and current for all laboratory staff. **3. Health and safety programme** **4. Accident/incident reporting programme** **5. Emergency response plan**: actions including notification list spill/contamination in lab, release from lab, and theft of agent. **6. Agent inventory management programme** **7. Waste management policy** **8. Security programme**: laboratory biosecurity for preventing unauthorised access to FMDV.	**Requirements:** **1.** SOPs and training materials cover **laboratory safety and laboratory biosecurity**. Routine use of Good Microbiology Practices is required of all staff. **2. Disinfection, decontamination, destruction** SOPs are available for all laboratory sections for both solid and liquid wastes. **3. Transport**: the laboratory uses an externally trained and certified staff member for packaging and shipping specimens and infectious substances to the regional reference laboratory. **4.** The **laboratory response plan** has been prepared and includes steps required for containment of an FMDV spill, and steps for notification and control following inadvertent movement of untreated waste materials from the laboratory. **5. Accident/incident reporting**: the laboratory safety officer is responsible for reviewing accident reports submitted by staff. Each accident and immediate response is reviewed, changes made as necessary to prevent a repeat occurrence, staff are notified of the changes, and an audit is scheduled to document effectiveness of the correction. **6. Audit**	**Requirements:** **1. Biocontainment** **2. Separation of incompatible activities** **3.Equipment maintenance, calibration, certification** current **4. Facility security**.	**Requirements:** **PPE**: dedicated laboratory clothing is used at all times in the laboratory, is never removed from the laboratory and is laundered on site.
In the Laboratory **Necropsy:** environment contaminated with fluids, low risk of exposure to outside environment.	**Assessment findings**: 1. Reporting plan FMDV positive animals/herds and contact list (names and numbers of animal health authority) is current.	**Assessment findings**: 1. Staff have been trained by the regional reference laboratory in the technical methods and safe handling requirements	**Assessment findings**: 1. All FMDV handling and diagnostic testing is conducted in a biosafety cabinet. When not in a cabinet, all	**Assessment findings**: Laboratory coats and gloves are required to be worn when working in the receiving or technical areas of the laboratory.

RISK ASSESSMENT (Likelihood and Severity)	RISK MANAGEMENT Administrative Controls	RISK MANAGEMENT Operational Controls	RISK MANAGEMENT Engineering Controls	RISK MANAGEMENT Personal Protective Equipment
Handling of specimens: **u**nknowns via diagnostic submissions including vesicular fluids, saliva (probing), vesicular epithelium containing potentially high virus load. (High risk for laboratory contamination.) Blood and serum (low risk) **Volumes and concentrations:** Anticipate 1200 diagnostic and disease control cases per year; archive 120 × 0.25 ml aliquots at ≥ 10^5 $TCID_{50}$/vial. (Low risk while disease remains endemic. At later stages of eradication effort, risk will progress to high risk). Amplification in cell culture; short and long-term storage of viral isolates (Moderate Risk while disease remains endemic. At later stages of eradication effort, risk will progress to high risk justifying elimination of routine on-site amplification in cell culture and long-term archive of isolates). **Diagnostic test methods:** Identification and characterisation of the agent: Virus isolation, antigen detection (ELISA), nucleic acid detection (real-time PCR). Serology: ELISA, CF, virus neutralisation (VN). (Note: as eradication progresses the risk of amplifying virus and	2. Training and competency in Good Microbiology Practices is current for all staff. Laboratory policy requires that staff agree to not come in direct contact with susceptible species for 96 hours after working with FMDV diagnostic cases and assays. 3. Employee health and safety programme. FMDV is not a human pathogen. 4. Accident/incident reporting programme in place; covers unintentional laboratory contamination associated with diagnostic specimens and derived materials (e.g. FMDV cultures). 5. Response plan addresses accidental and intentional release of FMDV. 6. Agent inventory management plan addresses access, secure storage, transfer, and destruction. Inventory management plan requires annual audit and reconciliation of inventory records. 7. Waste management policy addresses carcasses, tissues, fluids, and all laboratory wastes containing potentially infectious material. All potentially infectious laboratory wastes are autoclaved or incinerated prior to removal from the site. *Gap: cell culture flasks are accumulated in the un-restricted glass-washing/autoclave area prior to disinfection/destruction. Policy and procedure change is being*	for FMDV. Proficiency tests have been successfully passed. SOPs for the handling, testing, archive, and destruction of FMDV and related case materials have been prepared, reviewed by the regional reference laboratory, and used in the training of staff. 2. Decontamination, inactivation, and destruction protocols are in place for all laboratory areas. Specific pH and temperature requirements for inactivation of FMD virus are included. 3. External training and certification was obtained for one staff member responsible for packaging and shipping to reference laboratory. A second individual is currently scheduled for international packaging and shipping training. 4. A laboratory response plan has been prepared, including steps for containment of an FMDV spill, and steps for notification and recovery or destruction following inadvertent movement of untreated waste materials from the laboratory. *Gap: the laboratory has not had an exercise to test the response plan. Additionally the plan does not address the potential for intentional misuse of FMDV: these issues will gain importance as the disease control effort nears completion, and so will be corrected.* 5. The Accident/Incident Reporting process is applicable to work with FMDV. 6. Audit of FMDV biorisk control measures will be included with the laboratory quality system audits (2 per year).	FMDV specimens or assay materials are in a closed container. Note: the regional reference laboratory uses additional measures including FMDV-dedicated rooms with air-lock entry. As the laboratory does not have these facilities, the risk assessment will be reviewed with consideration given to transferring case materials and non-serology FMDV testing to the regional laboratory as the eradication effort progresses. 2. Separation of incompatible activities: The virology testing area where FMDV specimens are handled is separated from other areas of the laboratory by closed doors posted with restricted access signage. A dedicated incubator is used for amplifying FMDV reference viruses and for virus neutralisation assays (e.g. sources of high concentration of FMDV). The incubator is cleaned and decontaminated at the end of each work week. Real-time PCR tubes are not opened following amplification steps. Note: as the eradication effort progresses toward completion, the amplification of reference virus for PCR controls and for VN assays will be discontinued. The risks associated with all testing requiring live virus will be assessed, with the option of transferring samples and testing to the regional reference	Laboratory PPE is not worn outside of the technical areas of the lab. Laboratory wear inadvertently contaminated with FMDV is autoclaved prior to being laundered. Note: additional measures including dedicated clothing and showering after work with the agent are used in the regional reference laboratory. This facility does not have shower facilities, so as the eradication effort progresses toward completion, the risk assessment will be reviewed with consideration given to transferring case materials and non-serology FMDV testing to the regional laboratory.

RISK ASSESSMENT (Likelihood and Severity)	RISK MANAGEMENT Administrative Controls	RISK MANAGEMENT Operational Controls	RISK MANAGEMENT Engineering Controls	RISK MANAGEMENT Personal Protective Equipment
maintaining live FMDV for use in the VN assay will no longer be justified and will be discontinued). **Research:** No experimental work to be conducted on site. Isolates to be transferred to international reference laboratories only. **Viral isolate archives:** Short- and long-term storage of isolates. (Low risk while disease is endemic, progressing to high risk for intentional misuse as eradication of disease nears completion - see Security risks.)	*implemented to insure inactivation of virus prior to transferring the flasks from the virology laboratory* (*e.g. bleach*). 8. Laboratory biosecurity includes signage noting authorised access only to testing and storage areas. Visitors are allowed only with a laboratory escort and prior permission of the laboratory director or his designee. (Note: as eradication progresses, more stringent access control is justified, e.g. padlock or equivalent to be added to archive freezer).	Review of the FMDV risk assessment and biorisk management plan will occur at 14 months following initiation of the FMDV testing or earlier should there be changes made to the facility or to any FMDV-related SOPs or laboratory procedures.	laboratory being given a high priority. 3. The laboratory has maintenance contracts for Biosafety cabinets and thermocyclers. Calibration is performed by a commercial vendor for pipettors and CO_2 incubators. 4. Facility Security: Staff and visitors enter the laboratory grounds via a locked gate in a perimeter fence. The laboratory external doors are locked after business hours. The gate and doors are posted with signage stating "authorised individuals only".	
ECONOMIC RISKS				
Endemic in region: Cattle, sheep, and wildlife (hoofstock).				
Trade barrier: Due to endemic status, there is no current trade. (Note: goal of eradication is to open markets for wool and hides. As eradication effort nears completion the risk of handling the agent in the laboratory will progressively increase, at that time the laboratory must re-evaluate on-site testing and options for transfer of samples to a regional reference laboratory.	Update for current risk assessment is scheduled for 14 months from initiation of control programme, assuming that the disease prevalence will significantly decrease and the severity of economic impact from a laboratory release of FMDV will amplify to high risk.			

RISK ASSESSMENT (Likelihood and Severity)	RISK MANAGEMENT Administrative Controls	RISK MANAGEMENT Operational Controls	RISK MANAGEMENT Engineering Controls	RISK MANAGEMENT Personal Protective Equipment
ENVIRONMENTAL RISKS				
Stabile in environment: YES. Survives drying, may persist for days to weeks in organic matter under moist cool conditions; may persist in contaminated fodder and environment for 1 month (temperature, pH dependent).	Policy regarding recycling/re-use of expendable supplies (e.g. plastic culture flasks) has been modified to state re-use is never allowed for laboratory supplies used in FMDV detection and diagnosis; FMDV related laboratory wastes are placed in a biohazard bag and decontaminated at the end of each day to ensure they are never sent to landfill without prior treatment.	SOP on incineration (destruction) of solid laboratory wastes is in place; SOP on autoclave and chemical inactivation of liquid wastes is in place. Temperature and pH requirements for inactivation of FMDV are included.	Autoclave and incinerator available on-site. Indicator strips used with each run of the autoclave to ensure proper inactivation was achieved.	
SECURITY RISKS				
Short- and long-term storage of isolates. (Low risk while disease is endemic, progressing to high risk for intentional misuse as eradication of disease nears completion - see Security risks.)	Security policy requires visitors to sign a log, be escorted and not allowed in direct contact with diagnostic samples or tests. Note: FMDV has been identified by the international community as a potential biothreat agent.	An inventory log has been created to identify each vial of virus archived, and matches the identification on each vial. The log is electronic and is password protected. Gap: a pre-determined schedule for comparing the inventory to the inventory log has not been formally documented.	The virus inventory is stored on a designated shelf in a freezer with access restricted by signage to authorised staff. *Gap: a padlock is needed to further secure the virus archive.*	

Risk communication

Notification to appropriate animal health authority

The laboratory is planning to begin diagnostic testing for Foot and Mouth Disease in order to support the national FMDV eradication effort. The laboratory has completed a laboratory biorisk assessment and has in place appropriate control measures to prevent release of the agent from the laboratory. The designated laboratory contact for further information is _____.

Actions to be completed:

1. In consultation with the national animal health authority identify responsible person(s) and develop a communication message to be activated in the event of a laboratory spill or accident resulting in the release of FMDV from the laboratory.

2. In consultation with the national animal health authority and security agency as appropriate, identify responsible person(s) and develop a communication message to be activated in the event of theft or apparent deliberate release of FMDV from the laboratory.

Verification, corrective actions, and continuous improvement

Actions to be completed:

Training and exercises are to be scheduled in order to practice procedures for spill decontamination and for proper use of biosafety cabinets, autoclaves and incinerators; and for the proper response and notification procedures should a security breach be detected. Periodic self-assessment and review of standard operating procedures by the biorisk manager and laboratory staff are to be scheduled and completed at an approximate 6-month interval in coordination with the laboratory's quality system audit process. Reporting and documentation of biosafety or biosecurity incidents and breaches involving the FMD virus will automatically trigger a re-assessment of the FMD laboratory biorisks. All incidents will be reviewed by management, the biorisk manager, all impacted staff, and the applicable biosafety committee in order to correct the problem and to identify opportunities for improved laboratory practices and implementation of biorisk control measures.

NB: First adopted in 2014.

SECTION 2.2.

VALIDATION OF DIAGNOSTIC TESTS

INTRODUCTORY NOTE ON WOAH VALIDATION RECOMMENDATIONS

WOAH has adopted a formal standard entitled Validation of diagnostic assays for infectious diseases of terrestrial animals*, referred to as the WOAH Validation Standard. Its most recent version, adopted in May 2023, may be found as chapter 1.1.6 of this* Terrestrial Manual.

Section 2.2 Validation of Diagnostic Tests *deals with the use of the WOAH Validation Standard and its implementation for specific requirements such as different types of assay* (*antibody, antigen or nucleic acid detection*), *and an elaboration of some of the tools used in validation studies* (*measurement of uncertainty, statistical approaches, reference panels*). *There is also a chapter addressing some of the particular challenges in validating tests for wildlife species. All of the chapters have been written by experts in the respective fields, and have been subjected to an extensive process of consultation in arriving at the final texts.*

None of these chapters should be used in isolation*. Each is designed to complement and inform the application of the WOAH Validation Standard to specific situations.*

NB: FIRST ADOPTED IN 2014.

CHAPTER 2.2.1.

DEVELOPMENT AND OPTIMISATION OF ANTIBODY DETECTION ASSAYS

INTRODUCTION

The WOAH Validation Recommendations in Section 2.2 Validation of diagnostic tests *of this* Terrestrial Manual *provide detailed information and examples in support of the WOAH Validation Standard that is published as Chapter 1.1.6* Validation of diagnostic assays for infectious diseases of terrestrial animals*. The Term "WOAH Validation Standard" in this chapter should be taken as referring to that chapter.*

Detection of antibodies that are elicited in response to infectious agents or their components constitutes an indirect means of laboratory-based disease diagnosis. The most common antibody detection methods are classical virus neutralisation test (VNT), enzyme-linked immunosorbent assay (ELISA), haemagglutination inhibition (HAI) and the complement fixation test (CFT). Other, less common, antibody detection tests are the agar gel immunodiffusion (AGID), the indirect fluorescent antibody test (IFAT), the serum agglutination test (SAT), the latex agglutination test (LAT), and the microscopic agglutination test (MAT). More recent novel methods include biosensors, bioluminometry, fluorescence polarisation, chemoluminescence and lateral flow devices also known as point of care or pen-side tests. Other immunological assays that use antibodies in antigen detection tests are described in Chapter 2.2.2.

When considering a candidate assay type for disease diagnosis, one should include antibody detection assays because of their practicality, ease of sample collection and preparation, generally good diagnostic performance characteristics, suitability for automation (high-throughput), low cost and fast turn-around time. They are particularly useful for processing large numbers of samples in epidemiological and population studies, or for mass diagnosis and surveillance programmes. Antibody assays are also widely used for export, import and trade of animals, and still represent the majority of WOAH recommended tests for international trade.

A characteristic of antibody assays is their capacity to indicate prior exposure to an infectious agent in the absence of detectable organisms or their analytes. They are also adaptable to a variety of matrices, such as serum, plasma, whole blood, milk, lacrimal secretions and saliva. Immunoglobulin isotype or subclass-specific test systems may selectively target early or late immune responses, e.g. IgM and IgG, respectively. Specifically designed detection systems allow differentiation between responses to vaccine and field strains and are available as commercial kits, e.g. the detection of antibodies to classical swine fever virus in pigs. Competitive or blocking formats allow use of the same basic assay for a variety of animal species while other formats are species specific. Many types of chemical or physical indicators are used to indicate the presence of specific antibody in a specimen (chromogens, fluorochromes, agglutinins, among many others). Because of the large number of antibody detection methods available, it is not possible to describe the best practices for validation of each of these assay types in this chapter. The most widely used antibody detection system, the ELISA, will therefore be used as an example for application of best practices in antibody assays. Most of the basic processes used to validate other types of assay systems will become evident by extension of those used to validate ELISAs.

A. ANTIBODY DETECTION ASSAY DEVELOPMENT PATHWAY

1. Intended purpose(s) of the antibody assay

The first consideration in assay development is to define clearly the specific purpose and application of the test to be developed. Many decisions in developing assays will be based on these first considerations. For antibody detection assays (hereafter in this chapter designated as "antibody assays") such as ELISA, such knowledge will guide the selection of the most appropriate type of antibody detection system to achieve the intended purpose. Many factors related to the assay's intended purpose, use, and suitability need to be taken into account (see the WOAH Validation Standard for other possible purposes).

The six basic intended purposes for diagnostic assays are stated in the WOAH Validation Standard, and listed in the footnote to Table 1 below. Because antibody assays have such a broad range of applications, and can be configured for very specific purposes, it is useful to consider and evaluate several parameters when establishing the specific purpose(s) for the candidate assay. Table 1 summarises characteristics of antibody assays when applied for different purposes. Consideration of these characteristics will provide guidance in establishing the specific purposes for which the candidate assay will be fit.

Note – The reader is advised to read Section B.4. *Programme implementation*, as a primer for the following discussions. That section describes the inter-relationships between diagnostic sensitivity and specificity, false positive and negative test errors, and positive and negative predictive values. For a more in-depth discussion of predictive values as a function of prevalence, see Jacobson, 1998.

Table 1. Determinants of an antibody assay's fitness for its intended purpose

Assay characteristics	*Determinants of fitness for purpose*						
	*1**		*2**	*3**	*4**	*5**	*6**
	a	b					
Diagnostic sensitivity (DSe)	+++	+++	+++	+++	+++	+	+
Diagnostic specificity (DSp)	+	+	+	+	+++	+	+++
Positive predictive value (PPV)	+	+	+	+	+++	+	+++
Negative predictive value (NPV)	+++	+++	+++	+++	+++	+	+
Throughput capacity	+	+++	++	+	–	++	++
Turn-around time of test	+	+	+	+	+++	–	+
QA capability	+++	+++	+++	+++	+++	+++	+++
Reproducibility	+++	+++	+++	+++	+++	+++	+++
Repeatability	+++	+++	+++	+++	+++	+++	+++

Other characteristics such as the technical sophistication of the assay, and the skill required for interpretation will be related to the disease or infection under investigation.

Symbols: +++ = essential; + = of less importance; – = not important.

*Basic purposes for which an assay may be deemed fit: 1. Contribute to the demonstration of freedom from infection in a defined population. 2. Certify freedom from infection or presence of the agent in individual animals or products for trade/movement purposes; 3. Contribute to the eradication of disease or elimination of infection from defined populations; 4. Confirmatory diagnosis of clinical cases (includes confirmation of positive screening test); 5. Estimate prevalence of infection or exposure to facilitate risk analysis; 6. Determine immune status in individual animals or populations (post-vaccination)

1.1. Purpose 1

For disease freedom categories as given in purposes 1a and 1b (Table 1), antibody screening tests of high diagnostic sensitivity (DSe) are the tests of choice. As indicated in the purposes above, these tests would be applied to populations that have an apparent prevalence of zero. Tests of high DSe demonstrate low false negative (FN) rates and when applied to low prevalence populations, the negative predictive value (NPV) is at its highest level. However, DSe and diagnostic specificity (DSp) are usually inversely related and as such, a decrease in DSp will result in an elevated false positive (FP) rate. Other considerations, if

this is to involve a continuous volume of surveillance samples, would include high throughput, low cost and technical simplicity. All screening test positive results should be subjected to some form of confirmatory testing to evaluate their true status. Confirmatory tests characteristically have high DSp and therefore a low FP rate. These tests are often more sophisticated, more costly and may require enhanced interpretive skills.

If demonstration of freedom from infection is to be achieved after an outbreak, in which vaccination has been used for disease control, then screening of massive numbers of sera is often required. In addition to the considerations above, this also necessitates an antibody detection test which is able to distinguish between infected and vaccinated animals (i.e. a DIVA [differentiation of infected from vaccinated animals] test). At the same time an antigen or nucleic acid detection test may be warranted in some situations to prove that shedding and/or circulation of the infectious agent has ceased.

1.2. Purpose 2

If the purpose is to qualify individual animals for international movement, antibody screening tests of high DSe are again the tests of choice. The same rationale as stated above applies with respect to the NPV. Again, all positive reactors will need to be subjected to some form of confirmatory testing to evaluate their true status or may be excluded from shipment without further testing. In cases where borderline positives are observed, it may be wise to request a repeat sampling of the animal(s) at a suitable time interval to ensure that herd/flock has not been very recently infected.

1.3. Purpose 3

If the purpose of the test is the eradication of disease or elimination of infection from defined populations, antibody screening tests of moderate to high DSe are the tests of choice. However, the rationale is slightly different in that the testing will likely be done at herd or compartment level. At the beginning of the campaign, when the disease prevalence is high, moderate DSe and DSp are suitable as both FP and FN rates are less relevant at this juncture and a moderate level of test error is tolerable. Depending on the nature of the disease and rapidity of spread, high throughput and fast turn-around-times may become critical. Usually decisions are made without confirmatory testing at this point.

In the latter stages of the campaign, a higher DSe is warranted as the FN rate becomes the more critical factor. Much like Purposes 1 and 2, positive reactors will need to be subjected to some form of confirmatory testing to evaluate their true status. In these latter stages, antibody detection tests are often applied in conjunction with antigen and/or nucleic acid detection systems to detect subclinical cases and possibly, latent carriers.

1.4. Purpose 4

For the confirmatory diagnosis of clinical cases, antibody tests of high DSp are the tests of choice. In these cases, the idea is to minimise the FP rate and enhance the PPV of the test. As a general rule, infection is well established and the immune response is usually well underway. In some situations it may be preferable to carry out a screening test of high DSn but a lower DSp, then following up positives with a high DSp confirmatory test. For some clinical cases, e.g. vesicular diseases in terrestrial animals, several tests may be required to rule out select pathogens that present similar clinical signs. In some cases, antigen and/or nucleic acid detection tests may be a better choice for confirmation of clinical cases provided that they offer a fast turn-around-time. A prime example would be highly pathogenic avian influenza infections where mortality may occur before an immune response is even detectable.

1.5. Purpose 5

For estimates of prevalence of infection or exposure to facilitate risk analysis, e.g. for health surveys, herd health status and to monitor disease control measures, antibody tests of moderate DSe & DSp are the tests of choice. In general, this would balance both FN & FP rates and result in a more accurate estimate of the true prevalence of infection in the target population. However, if accurate estimates of both DSe and DSp have been established, statistical approaches can be used to minimise bias attributable to FN & FP rates (see Chapter 2.2.5 *Statistical approaches to validation*).

1.6. Purpose 6

For the determination of the immune status in individual animals or populations, e.g. post-vaccination, antibody tests of high DSp are required. Such tests have very low FP rates and as such provide a high degree of confidence in the PPV of the result. For use in individual animals, the use of virus neutralisation (VN) tests in cell culture for the detection of vaccine-induced neutralising antibodies against rabies virus in dogs and cats would be a prime example of a test with high DSp used for expression of titres in international units. However, these tests are technically sophisticated, expensive to maintain and run, and require strict biosafety procedures. For larger volume applications, such as monitoring regional vaccination programmes, ELISA-based tests would be more applicable, given their simplicity, cost effectiveness and high throughput. The same DSp considerations should be applied to these types of tests.

The experience of laboratory diagnosticians is not only essential in the choice of an appropriate test that will achieve the desired purpose, but is also required to determine reliably the scientific limitations of an assay and practical considerations such as cost, equipment and reagent availability, throughput capacity of the laboratory and test turn-around-times.

2. Assay development – experimentation

2.1. Reference materials, reagents and controls

Designing the method

- Has the design been shaped by the intended purpose of the assay?
- What is the specific application?
- What are the types and statistically relevant numbers of samples to be tested? (See Chapter 2.2.5)
- Will the test be field or lab based?

2.1.1. Test samples

Samples to be tested in antibody assays should be handled as described in Chapter 1.1.2 *Collection, submission and storage of diagnostic specimens*. The sample matrix in which antibodies are usually detected is serum, but may also include plasma, whole blood, milk, meat juice, egg yoke, lacrimal secretions and saliva.

2.1.2. Reference Standards

Antisera directed against the reference strain of a pathogen are known as reference sera or reference standards (Wright *et al.,* 1993; WOAH Validation Standard; Section 1.4 of Chapter 2.2.6 *Selection and use of reference samples and panels*). Such sera containing antibody of known concentration/activity are useful in the initial development of an assay. For a number of WOAH listed diseases, (e.g. avian influenza, foot and mouth disease, classical swine fever, etc.) international reference standards are available through WOAH Reference Laboratories and Collaborating Centres. When not available from other sources, it may be necessary to produce in-house reference standards against which working standards (process or quality controls) are calibrated.

2.1.3. Positive and negative reference panel

These sera, containing concentrations of antibody over the intended operating range, (also known as dynamic range) of the assay, should be used throughout the development and standardisation of an antibody assay. It is recommended that they be prepared in sufficient quantities so that they may be used in various aspects of validation. These samples should represent known infected and uninfected animals from the population that eventually will become the target of the validated assay. They should preferably be derived from individual animals, but they may represent pools of samples from several animals (Chapter 2.2.6).

2.1.4. Monoclonal antibody reagents

The advent of monoclonal antibodies has greatly enhanced enzyme immunoassays. Whereas polyclonal anti-immunoglobulin conjugates are used in most indirect ELISAs, monoclonal antibody conjugates can be directed to specific immunoglobulin isotypes. Depending on the immunoglobulin epitope targeted, many of these monoclonals can be effectively used to detect

antibodies in related species, e.g. ruminants. Using monoclonal conjugates to either light or heavy chain epitopes can effectively modulate the DSp and DSe of the indirect ELISA.

Monoclonal antibodies are best known for their application in competitive or blocking ELISAs. In this case, the monoclonal specificity is directed to epitopes on the pathogen in question. Depending on the epitope targeted, the analytical specificity of the assay can be modulated.

Critical points to be addressed:

- Have you considered that concentrations of analyte in matrix significantly impact the lower limit of antibody detection and the operating range of the assay?
- Are the required antibody reagents (mono/polyclonal) available?
- Is available antigen sufficiently purified?
- Are reagents commercially available? If not, is it practical to produce them in-house?
- Are reference standard reagents available? If not, how are you going to resolve this deficiency? (See WOAH Validation Standard, Section A.2.6.)

Monoclonal antibodies can also be used in sandwich ELISAs, either for trapping antigen to the plate or for subsequently detecting antigens that have been trapped. Depending on the size and complexity of the antigen in question, it is sometimes preferable to use a polyclonal antibody preparation for trapping as they generally contain antibodies of high binding affinity.

2.1.5. Antigens

Aspects affecting choice of test

- Is the assay to be used for screening or confirmatory purposes, or both?
- Will it be used for one or more species? Which ones?
- Is the test intended for detection of early or late infection?
- Will the test be used to measure serotype- or subtype-specific antibodies?
- Will the assay be used to confirm sero-conversion after vaccination?
- Will it be a DIVA assay (differentiation of infected from vaccinated animals)?
- Will the test be applied to trade?

Antigens used in ELISAs are of critical importance to diagnostic performance given a particular application. Antigens expressing highly conserved epitopes, such as those found in some viral matrix or nucleoproteins, are generally useful in group-specific assays, such as ELISAs for the detection of responses to all Influenza A viruses. Other antigen epitopes can be used to restrict detection to certain serotypes. The choice of antigen must be carefully researched and considered.

Crude antigen preparations like cell lysates have had widespread use in the past, and are still deployed for some assays. However, antigens improved greatly as purification techniques advanced, e.g. affinity chromatography. Further improvements were achieved through the application of molecular cloning. Recombinant antigen technologies have greatly enhanced all aspects of ELISA performance, from analytical through diagnostic characteristics.

2.2. Design of test method

In designing a test, its intended application will influence the choice of assay format that is best suited for the task. For example, if its use is primarily for surveillance, then the type of ELISA needs to be conducive to achieving high DSe, as described in the 'Purposes' above. If, however, the screening assay's DSe is set so high that it generates many false positives, then a companion confirmatory test should also be considered at the same time. Many ELISA formats are available, each with their advantages and disadvantages that allow customisation of assays for very specific purposes (Table 2).

Practical matters in selecting an assay format

- Is high-throughput essential? Will it be automated?
- What is the anticipated turnaround time? Is that suitable?
- What level of sophistication is needed to run the assay?
- What skills are required to interpret the test?
- Will that assay be feasible for use in my laboratory?
- Will it be easily transferrable to other laboratories?

Important factors that influence the choice of an antibody assay format are availability of reagents and likely continuity of supply, not only for the design and optimisation stage but for operational scale application of the test. A limitation may be the unavailability of relevant antibody reagents for a particular format, e.g. competitive or blocking formats generally require antigen-specific monoclonal antibodies. Another example would be the need for an effective capturing antigen: a rather crude antigen may be acceptable for use in a sandwich-based ELISA screening assay, whereas a purified antigen would be necessary for a confirmatory assay. Other important considerations for choosing a particular ELISA format are which antibody isotypes, concentrations, avidities and antigenic specificities are diagnostically relevant; which antigen, and in particular which epitopes are relevant; and what is the desired operating range of the assay. All will play a large role in selecting a particular type of ELISA (Table 2). If it is anticipated that the test will be used in different species, including wildlife, a competitive/blocking format may be useful. Deciding on an assay format also requires that application of the assay be considered. Questions that should be addressed are detailed in the box above on "*Practical matters in selecting an assay format*" and practical questions in the boxes below Table 2. It is essential to deal with such questions at this point in assay development as they are essential to a positive outcome and application.

Table 2. ELISA formats: advantages and disadvantages*

Type of ELISA	*Advantage*	*Disadvantage*
Indirect – bound Ab detected by anti-species conjugate or by Protein A/G conjugates	Use and availability of high variety of antispecies-specific conjugates often targeting particular antibody subsets, such as anti IgM, IgG1, IgG2, etc. Protein A and Protein G conjugates have a wide species specificity and may give lower background signals than anti-Ig reagents. Wide use for screening large numbers of samples	Variation in degree of nonspecific binding in individual sera To compensate for this problem high starting dilutions are required This can lead to a decrease in DSe in comparison to competitive/blocking formats Can only be used for one or a few species at a time
Sandwich – Ag presented on a solid-bound-phase capture antibody	The capture antibody on the solid phase can help to orient the antigenic molecule, which improves the chance that the sample antibody will bind. Unpurified antigen preparations can be used because capture antibody selectively binds crude antigen. Pre-coating with capture antibody can reduce the potential for subsequent binding of nonspecific proteins during the test.	Antigens must have at least two antigenic sites or epitopes which limits this type to relatively large antigenic complexes or more complex proteins Size and spatial relationship of epitopes can affect the assay
Competition (indirect and sandwich types) – Test antibody in sample mixed with pre-titrated detection antibody, then added to wells coated with capture antigen, either in direct or inhibition/blocking format.	Easy adaptation for use as antibody detection tests When highly specific MAbs are used the antigen does not have to be highly purified Can be used in different species for which no conjugated antibodies exist Advantage of competitive/blocking sandwich type relies on antigen capture Sera can be tested in low dilutions without risk of interference due to non-specific antibodies binding. This may contribute to a higher sensitivity of this format Different antibody concentrations can be used to favour either analytical sensitivity or specificity. This is particularly relevant for assays using polyclonal antibodies which are much more affected through the use of different dilutions of sera	Generally more steps and more optimisation may be needed, e.g. pre-titration and optimisation for liquid and solid phase reagents. Higher level of technical sophistication required

*Primary source is Crowther (2001).

2.3. Proof of concept experiments (feasibility studies)

After choice of an ELISA format, initial experiments are designed to determine if the proposed assay is viable. A reference panel such as described in Section A.2.1.3 should be tested in the prototype assay. If a reference standard is to be used for normalisation of test data, it should be selected and incorporated at this point in assay development. To provide continuity in data assessment throughout, both the reference panel and any reference standards should be included in all remaining aspects of the validation studies. The reference panel used in the feasibility study should span the entire anticipated operating range of the candidate assay and be run in replicates as a quick check for repeatability.

Proof of concept

- Was the feasibility study conducted with at least 4 to 5 samples spanning the operating range of the assay?
- Did you include one or more reference standards if required for data normalisation?
- Was separation of results between negative, low positive and high positive samples adequate?

The assay should achieve good separation in OD values, spanning the operating range of antibody activity. Adequate separation is particularly important between the negative and low positive samples. The lower OD range should be 0.1 or less for the negative control in indirect ELISAs, or for the strong positive control in competitive/blocking ELISAs. OD values at the upper end of the operating range should not exceed 2.0, as above this value plate readers become rather inaccurate. If the assay appears promising, optimisation is the next step.

2.4. Samples and data expression

2.4.1. Preparation and storage serum panels for optimisation studies

A best practice for antibody assays to select several (a minimum of four to five) serum samples that range from negative to high levels of antibodies against the infectious agent in question. These samples are initially used in experiments designed to demonstrate proof of concept. A large volume (e.g. a minimum of 10 ml) of each serum sample is acquired and divided it into 0.1 ml aliquots for storage at or below –20°C. One aliquot of each sample is thawed, used for experiments, and ideally then discarded. If it is impractical to discard the aliquot, it may be held at 4°C between experiments for up to about 2 weeks; however, there is a possibility of sample deterioration under these circumstances. Then, another aliquot is thawed for further experimentation. This method provides the same source of serum with the same number of freeze–thaw cycles for all experiments (repeated freezing and thawing of serum can denature antibodies so should be avoided). Also, variation is reduced when the experimenter uses the same source of serum for all experiments rather than switching among various sera between experiments. This approach has the added advantage of generating a data trail for the repeatedly run samples.

After the initial stages of assay validation are completed, one or more of the samples may be suitable as a reference standard for data expression and the entire panel may be used for repeatability assessments both within and between runs of the assay (Jacobson, 1998). They may also serve as in-house working standards, i.e. quality or process controls given that their reactivity has been well characterised; such controls provide assurance that runs of the assay are producing accurate data (Wright *et al.,* 1993).

2.4.2. Normalisation of results and their expression

An optical density (OD) reading in ELISA is a measurement of colour development that is a function the amount of antibody present in a sample. Because colour development is a function of a reaction of enzyme and substrate in the presence of a chromogen, results from day to day are subject to variation attributable to external factors such as temperature, reaction time, etc. Comparison of OD results for the same samples between runs of an assay in the same laboratory, or between laboratories, lacks precision because of variation in results of reference standards included in each run of the assay. Therefore, OD results of test samples need to be adjusted as a function of the OD(s) of one or more reference standards in a specific assay run. This process is known as “normalisation” of ELISA results (see the WOAH Validation Standard, Section A.2.7 for

details). The method of normalisation and expression of data should be determined, preferably no later than at the end of the feasibility studies.

OD values may be expressed in several ways (Wright *et al.,* 1993). A simple method is to express all OD values as a percentage of a single high-positive serum control that is included on each plate. For such calculations, this control must yield results that are in the linear segment of the operating range of the assay. A more rigorous normalisation procedure is to calculate results from a standard curve generated by plotting observed OD values against concentration (or dilution) of antibody for several serum controls that span the range of antibody activity of the assay. It requires a more sophisticated algorithm, such as linear regression, log-logit, or 4 or 5 parameter logistic regression analysis, among others. This approach is more precise because it does not rely on only one high-positive control sample for data normalisation, but rather uses several serum controls, adjusted to expected values, to plot a standard curve from which the sample value is extrapolated. This method also allows for exclusion of a control value that may fall outside expected confidence limits.

2.5. Optimisation

For ELISAs, the most important variables that need to be optimised are concentration/dilution of antigen adsorbed to the solid phase, test serum working dilution, enzyme molarity, antibody-conjugate dilution, and substrate solution concentration. These are evaluated through checkerboard assessments (each variable compared against all other variables within one run of an assay that is repeated several times). Other variables that need consideration are pH and ionicity of reagents, molecular factors such as valency and epitope density of antigens, isotype of targeted antibody and antibody affinity. Precision of test results can be graphically depicted or expressed numerically by various statistical methods (Crowther, 2001). ELISA studies require that instrumentation (plate washers and readers, etc.) must be properly calibrated prior to use – part of the laboratory's quality control programme.

Optimisation and standardisation

- Have all critical reagents been tested against each other in checker board titrations?
- Did you find optimal concentration/dilutions for each reagent?
- Did you incorporate quality or process control procedures and reagents?
- Did you incorporate methods for normalisation of test data?

2.6. Inhibitory factors in sample matrix

Although ELISA antibody detection systems are rather resistant to inhibitory factors, the WOAH Validation Standard, Section A.2.4, and Greiner *et al.* (1997) provide descriptions of the type of inhibitors that could affect the assay. These references should be reviewed carefully to assure that all inhibitory factors are accounted for and controlled.

2.7. Calibration to reference standard sera

If international, national, or other-source reference sera are available, the assay should be calibrated to match the analytical sensitivity in terms of the metrological units ascribed to the calibration sera (Wright, 1998).

B. ASSAY VALIDATION PATHWAY

1. Stage 1 – Analytical performance characteristics

1.1. Repeatability

Analytical performance characteristics

- Has repeatability been established for a range of positive and negative samples within and between runs of the assay
- Have upper and lower control limits of the assay been established
- Have you defined ASe and ASp for this assay?
- Does the candidate assay compare favourably with a standard test method, based on objective quantitative and qualitative criteria?

Repeatability is the level of agreement between results of replicates of a sample, both within and between runs of the same method in one laboratory. The same or similar panel of samples used in the feasibility study is adequate. No less than three (preferably 5) samples covering the operating range of the assay, and of sufficient quantity for at least 20 runs of the assay over several days. Specifics of how the samples should be prepared and handled are provided in Chapter 2.2.6 and in the WOAH Validation Standard, Section B.1.1. It is valuable to include at least one reference sample in an indirect ELISA (a positive serum control) to which the test samples can be normalised by per cent of the positive control. The within run variation can be determined by the mean OD and coefficient of variation (CV) of the replicates of each sample. The CV should not exceed about 15% (with the possible exception of negative and very low positive samples which may have higher (and meaningless) CVs). If all of the samples have previously been calibrated to reference standards, and their expected ODs are thus known, the observed ODs for each sample in each run can normalised as a function of their expected ODs in linear regression analysis. This provides a correlation coefficient as evidence of closeness of fit to the expected value, and allows for normalised values to be plotted in control charts (Crowther, 2001).

1.2. Analytical specificity

Analytical specificity (ASp) is determined by testing sera from animals that are known to have been infected/exposed to all species/strains that the test should detect (Chapter 2.2.6, Section B.1). Cross reactivity with sera from animals infected with related species is used to evaluate the ASp. ELISAs are also subject to false positive results attributable to exogenous factors, such as nonspecific binding of serum or conjugate to the plastic surface that may require use of blocking agents. Care must be taken to eliminate this source of error. Blocking and competitive ELISAs may also suffer specificity problems due to stearic hindrance preventing proteins binding to their target sites.

1.3. Analytical sensitivity

Analytical sensitivity (ASe) is synonymous with the lower limit of detection (LOD) of antibody concentration in a sample. The different types of antibody assays vary considerably in their inherent limit in antibody detection. For instance, LODs for eight different types of antibody assays range from 1000 ng/ml (radial immunodiffusion) to 0.01 ng/ml (chemiluminescence) (Nielsen *et al.,* 1996). LODs are usually determined by endpoint dilution in which replicates (preferably 10) of each dilution in a $\log_2$ dilution series are run in the assay.

1.4. Standard test method comparison with the candidate test method

The candidate test method should be run in parallel with an WOAH or other accepted reference test method, using the same panel of samples on both, to determine whether the candidate method exhibits the same quantitative and qualitative characteristics as the standard method. Favourable comparability lends strength to the belief that candidate method will be a successful substitute for the reference method (see also methods comparison studies, Chapter 2.2.5).

2. Stage 2 – Diagnostic performance characteristics

DSe and DSp are the primary performance indicators of the validation process. Antibody assays are subject to the same general procedures to achieve estimates of DSe and DSp as required of all other assay types (see the WOAH Validation Standard, Section B.2 for essential details). The number of samples needed to establish these estimates for a particular antibody assay require a sampling design that considers many variables. This includes creation of a sample panel that is tailored particularly for the intended purpose of the assay (e.g. a screening versus confirmatory test). It also requires predetermined desired levels of DSe and DSp (indicating acceptable levels of false negative and false positive results), allowable error in the estimates of such DSe and DSp, and the confidence level required for these estimates.

The number of animals required to establish acceptable DSe and DSp estimates is a function of the level of confidence desired in DSe and DSp estimates and the accepted allowable error. For instance, for a pathogenic disease like FMD, it is necessary to reduce the likelihood that infected animals will be misclassified as uninfected, which reduces allowable error in the test result which, in turn, increases the number of samples needed to establish a high level of confidence in the DSe estimates. Alternatively, for a confirmatory assay it is desirable to reduce the likelihood that uninfected animals will be classified as infected. A high DSp is then desired with minimal allowable error, requiring a larger sample size of uninfected animals. All of these general issues related to sample size, confidence intervals and allowable error in the DSe and DSp estimates are described in the WOAH Validation Standard, Section B.2, with additional detail and tables of sample numbers required available elsewhere (Jacobson, 1998).

It is often challenging to obtain a sufficient number of well characterised sera to achieve estimates of DSe and DSp that are sufficient for the intended purpose of the assay. Initially, it may be a compromise between what is statistically meaningful and practically feasible, resulting in an assay that is provisionally recognised (WOAH Validation Standard, Section B.2.6). However, over time, with accumulation of more well characterised samples, the estimates of DSe and DSp may be strengthened (see Section 5.4 below).

2.1. The challenge in establishing accurate estimates of DSe and DSp for antibody assays

Antibody assays undergoing validation pose unique problems when attempting to assemble known positive and known negative samples in sufficient quantity to establish assay performance characteristics. Antibody is an indirect indicator of the presence of, or prior exposure to, an infectious agent or its components. Inferences from detection of antibody (or the lack thereof) depend on the host's qualitative and quantitative responses to the organism. Factors that affect the concentration and composition of specific antibody in serum samples are inherent to the host (e.g. age, sex, breed, nutritional status, pregnancy, immunological responsiveness) or acquired (e.g. passively acquired antibody, or active immunity elicited by vaccination or infection). Theoretically, samples from animals that represent all of these variables should be included in the panels used for establishing DSe and DSp estimates. Clearly, this becomes a daunting, if not impossible task. To surmount this problem, the initial sample panels should be representative of the majority of animals in the target population to achieve initial estimates of DSe and DSp. In reality, it is necessary to enhance DSe and DSp estimates after the assay has been implemented as more well characterised samples become available (see Section 5.4, below).

Diagnostic performance characteristics

- Are the criteria used to determine the positive and negative reference populations legitimate?
- Do the reference samples fully represent the population targeted by the assay?
- Were there difficulties in obtaining a sufficient number of samples? If so, how was the problem addressed?

Because it is often desirable to stretch the application of antibody detection assays to a huge number of animals spanning large geographical areas (e.g. as in screening assays for an entire continent), assembly of fully representative sample panels for such a large diagnostic window of variables may be nearly impossible. A useful alternative is to first establish DSe and DSp estimates for a rather homogeneous population of animals. If the assay is destined for use in disparate populations of animals, which may harbour a different infectious agent profile (with possibility of cross reactions not seen in the original targeted population), a reassessment of DSe and DSp may be necessary, drawing from data acquired using new sample panels that are representative of the population(s) targeted.

2.2. Reference animal populations

2.2.1. Animals of "known infection status"

Reference animals of known infected and known uninfected status are the ideal source of samples for determining DSe and DSp. However, such samples are rare and difficult to establish. The most familiar term for reference animals or samples used in establishing DSe and DSp is the so called "gold standard", a misnomer commonly used to classify almost any reference animal as infected/exposed or uninfected, with samples from such animals classified as positive or negative (see the WOAH Validation Standard, Section B.2.1–2.3).

Assay developers should be aware of the advantages, and particularly the pitfalls, associated with various methods that are used to classify reference animals as infected or uninfected. The samples from such animals are deemed either positive or negative, and collectively become the *reference standard* upon which the candidate assay's DSe and DSp are based. It is, therefore, crucial to carefully consider the validity of various reference standards as exemplified in the following four examples:

i) An unequivocal reference standard: presence of the agent in the host or evidence of definitive (pathognomonic) histopathology

If an infectious agent or definitive histopathological criterion is detected in an animal, this generally constitutes an unequivocal reference standard for that animal. Serum samples derived from such animals usually are considered to be unequivocal serum reference standards for determining DSe and DSp of the candidate assay. However, such samples may have their limitations. At the population level, a pathogen may be unequivocally present in some animals, but if the serum sample was taken from the animal early in the infection process, the immune response may not yet have produced detectable antibody. In this case, such serum samples used as reference standards would have been FN for the subset of animals in an early stage of infection. In contrast, for more chronic types of infection, using only reference animals that have confirmatory culture or histopathology may produce higher estimates of DSe than are realistic for the population targeted by the assay because the immune response will always be well established.

ii) A composite reference standard: verification of uninfected or unexposed animals

This standard is achieved by selecting reference animals from geographical areas where herd histories, clinical profiles, prior testing results and other parameters provide evidence suggesting the absence of the pathogen, and thus no specific host antibody response to the pathogen targeted by the candidate assay. These types of reference materials, their strengths and limitations are described elsewhere (Jacobson, 1998), and must be considered carefully when using samples from such sources for establishing DSe and DSp for a candidate assay.

iii) A relative reference standard: comparative serology

This standard is characterised by reference animals that have been classified for their infection status by comparison with the test results of another serological assay on the same samples. It often is the only practical source of reference material available for evaluation of a new serological test. If results of such a reference test are chosen as the standard for determining diagnostic performance characteristics of the candidate assay, the resultant estimates of DSe and DSp are useful only insofar as the reference test has documentable, established and acceptable performance characteristics. A deficiency of relative reference standards is that they have their own established levels of FP and FN test results, which are sources of error that will be compounded in estimates of DSe and DSp for the new assay. Generally, however, the use of other well described test methods is regarded as good practice to determine the status of reference animals, but only if the inherent bias introduced by the relative reference standard is accounted for.

iv) *An adjunct reference standard*: experimental infection or vaccination

(See the WOAH Validation Standard, Section B.2.3 for significant limitations of this type of standard.) In some cases, the only way to obtain positive samples is by experimental

infection. This approach is highly suitable to model the dynamics of the infection and to determine the 'diagnostic window' with the new assay. For example, it is possible to get estimates of the time interval between exposure to a pathogen and when antibody is first detectable, or when 25, 50, 75 and 100% of the infected animals return a positive test result. Nevertheless there are pitfalls in use of time-series data that must be avoided. Data representing repeated observations from the same animals cannot be used in calculation of DSe and DSe because the statistical models used to establish DSe and DSp require independent observations (only one sample from each anima). For statistically legitimate time-course studies, or when single samples are used from each of many experimental animals, the strain of cultured organism, route and dose of exposure, infection with other related, cross-reactive and non-related, non-cross-reactive organisms are variables which may produce quantitatively and qualitatively atypical responses which are not found in natural infections in the target population. Experimental conditions typically lead to an overestimation of sensitivity and specificity for example by artificially high challenge doses and by using specific pathogen free animals as negative controls.

The time point of sample collection (days post-infection) must be indicated. Sources and history of experimental animals should be described. The validation should not be based solely on experimental animals as they do not represent natural populations of animals subject to pathogens by natural exposure.

2.2.2. Latent-class models for estimation of DSe and DSp

For a discussion of this approach for estimation of diagnostic performance, see the WOAH Validation Standard, Section B.2.5 and Chapter 2.2.5.

2.3. Threshold (cut-off) determination

The procedures for establishing the cut-off between negative and positive results of antibody assays are as described in the WOAH Validation Standard, Section B.2.4.

3. Stage 3 – Reproducibility and augmented repeatability estimates

Reproducibility is the measure of precision of an assay when used in several laboratories located in distinct regions or countries using the identical assay (protocol, reagents and controls) to test the same panel of samples. Reproducibility assessments for antibody assays are not uniquely different from similar assessments for any other type of assay. Therefore the reader is directed to the WOAH Validation Standard, Section 3, for details on reproducibility analysis and for reference samples and panels to Chapter 2.2.6.

4. Stage 4 – Programme implementation

4.1. Interpretation of results and determination of predictive values

Best practices for programme implementation are general to all assay types (WOAH Validation Standard, Section B.4). However, as ELISA is often the assay of choice for surveillance programs to affirm absence of disease, or for eradication of disease or elimination of infection from defined populations, the issue of false positive results can be a significant problem even if the diagnostic specificity is very high.

A common misperception is that a test with 99% DSp and DSe will only mis-classify animals as FP or FN 1% of the time. The FN and FP rates vary depending on the prevalence of infection in the targeted population. False positive reactions in a disease eradication campaign can vary significantly from the beginning of the campaign when prevalence is relatively high (for example, 10%) to near the end of the campaign when it has decreased to 0.1%. The predictive values of test results then become very important. Predictive values are probabilities that a test result is truly positive or truly negative. In our example using an assay with 99% DSe and DSp for testing a population of animals with a 10% prevalence of disease, the predictive value of a positive test result (PPV) is 91.7%, meaning that there is a 91.7% probability that the animal is truly infected. The predictive value of a negative test result (NPV) is 99.9. When the prevalence drops to 5%, the PPV and NPV are 83.9% and 99.9%, respectively. However, if the prevalence drops further to 0.1%, by successfully removing infected animals from the population, the same test will produce a PPV of 9% and a NPV of 99.9%, meaning that there is only a 9% chance that a

positive test result is detecting a truly infected animal (of 1000 animals tested, only about 1 in 10 positive test results is indicative of an infected animal – the other 9 are false positive). So, if the test is intended for the purpose of eradication of a disease or elimination of infection from a population, the test developer is advised to consider moving the assay to a second cut-off that yields a higher DSp late in the campaign to reduce the probability of false positive reactions. It is instructive to examine a predictive value chart for assays of varying DSe and DSp, to visualise the effects of reduced prevalence on predictive values of an assay (WOAH Validation Standard, Table 2, and Jacobson, 1998).

5. Monitoring assay performance

5.1. Monitoring the assay

Once the assay is in routine use, internal quality control is accomplished by consistently monitoring the assay using quality control charts for assessment of repeatability and accuracy. Charts representing at least 30 runs will reveal trends or shifts in values of controls and standards. Lines representing the mean value of a control sample in at least 30 runs, plus/minus 3 standard deviations, are useful decision criteria for inclusion or exclusion of a run of the assay. The run is rejected if one control/standard exceeds ± 3 standard deviations (STD) or if 2 controls (or more) exceed ± 2 STD (Crowther, 2001). Decision criteria may need to be customised for a given assay because of inherent differences between assays attributable to the host pathogen system. Chapter 2.2.4 provides an example of how to apply measurement uncertainty for an antibody ELISA using a positive internal control sample.

Reproducibility of test results between laboratories should be assessed by External Quality Assurance at least once per year and is an essential requirement of ISO 17025 accredited laboratories. Membership in a consortium of laboratories that are interested in evaluating their output is valuable.

5.2. Minor modifications of the assay – replacement of depleted reagents

When quality or process control samples are nearing depletion, it is essential to prepare and repeatedly test the replacement samples. The replacement samples should be included in at least 10 routine runs of the assay, with their results normalised against the existing reference standard. The activity of the replacement control should be comparable to the replaced control. If the reference standard requires replacement, care must be taken to select a replacement that matches all of the original serum characteristics as closely as possible, thus allowing use of the replacement to normalise test results with comparable outcomes (see also Chapter 2.2.8 *Comparability of assays after changes in a validated test method*).

When other reagents such as antigen for capture of antibody, must be replaced they should be produced or procured using the same protocols or criteria as used for the original reagents. They need to be assessed using sera from routine submissions in 5–10 parallel runs that include the current and the new reagent(s). A panel of representative samples, such as a proficiency panel, is also a useful tool for assessing the comparability of the reagents (Chapter 2.2.6).

Monitoring assay performance

- Has the purpose of the assay changed?
- Has the epidemiology of the disease in question changed, e.g. prevalence, new serotypes or strains, etc.?
- Have critical reagents been changed, and if so, was comparability of the new reagents assessed?
- Are performance indicators included in day to day use of the assay (control charts, basic statistics)?
- Are upper and lower limits in control charts updated periodically as more experience with the control samples is achieved?
- Are test panels shared with other laboratories to assess reproducibility?
- Is proficiency testing included as part of continuing evaluation of the assay?

5.3. Major modifications of the assay – changing to a new ELISA type

If the assay is to be changed from, say, a sandwich ELISA to a competitive/blocking format, the assay will require revalidation because of the many variables that may affect the performance characteristics of the assay. For an assay considered for implementation in another geographic region, e.g. from the northern to the southern hemisphere, it is essential to revalidate the assay by subjecting it to sera from populations of animals that reside under local conditions. Evaluation of reference sera that represent those populations is done by using stages 3–5 in Figure 1 in the WOAH Validation Standard. It is the only way to assure that the assay is valid for populations that are of different composition compared with the original population targeted by the assay.

5.4. Enhancing confidence in validation criteria

Due to the extensive set of variables that have an impact on the performance of serodiagnostic assays, it is useful to expand the number of reference sera wherever possible, recognising the principle that error is reduced with increasing sample size. An expanded reference serum bank should be accumulated with well characterised sera, and used periodically to update estimates for DSe and DSp for the population targeted by the assay.

CHAPTER 2.2.2.

DEVELOPMENT AND OPTIMISATION OF ANTIGEN DETECTION ASSAYS

INTRODUCTION

The WOAH Validation Recommendations in Section 2.2 Validation of diagnostic tests *of this* Terrestrial Manual *provide detailed information and examples in support of the WOAH Validation Standard that is published as Chapter 1.1.6* Validation of diagnostic assays for infectious diseases of terrestrial animals. *The Term "WOAH Validation Standard" in this chapter should be taken as referring to that chapter.*

The detection and identification of an agent is confirmatory evidence of either infection with or disease caused by a particular pathogen. There are many different direct and indirect test methodologies available. Classical direct[1] agent detection assays include electron microscopy, light microscopy (*e.g. observation of unique histopathological or pathognomonic features, identification of parasites* in situ*, etc.*)*, virus isolation, bacterial culture and parasitic digestion techniques. Many direct techniques require secondary procedures to assist in the characterisation and identification of these agents* (*e.g. haemagglutination inhibition or virus neutralisation tests, special bacteria or fungal stains, etc.*)*. Representatives of indirect agent and in particular, antigen* (*Ag*) *detection tests include enzyme linked immunosorbent assays* (*ELISA*)*, immunofluorescence or immunoperoxidase assays, Western blotting techniques, micro-arrays, fluorescence activated cell sorting* (*FACS*) *and biosensors. Often direct and indirect methods are used in tandem, for example a direct technique may be used to isolate, enrich and/or extract the organism followed by indirect techniques to characterise and identify the agent.*

Practical matters in selecting an assay format

- Is high-throughput essential? Will the test be automated?
- Will the test be used as a herd test or for testing individuals?
- What is the anticipated turnaround time? Is that suitable?
- What level of sophistication is needed to run the assay?
- What skills are required to interpret test results?
- Will the assay be feasible for use in my laboratory?
- Will it be easily transferrable to other laboratories?

The examples given above vary widely in terms of laboratory requirements. Pen-side tests (*including lateral flow devices*) *may also be antigen detection tests. They are easy to use and were developed for testing of animals in the field but may have applications in laboratories. Cost, laboratory infrastructure, biocontainment/safety, technical sophistication, interpretation skills, turn-around time, throughput capacity, diagnostic performance characteristics, repeatability and reproducibility are important parameters which need consideration when selecting the most appropriate assay. They also vary with respect to suitability for different diagnostic applications.*

1 Definitions: In the context of direct and indirect detection of an analyte, the term "direct" is relevant to the organism or its antigens, e.g. direct detection by microscopy. The term "indirect" is relevant to the host response to the organism, (e.g., indirect detection inferred by detection of antibodies to the organism). In the context of diagnostic methods that are used to detect infection, microscopy is a means of direct observation of the organism, whereas using a reagent that infers the presence of the agent (such as an enzyme conjugated to a purified antibody that is specific for the agent) is an indirect method.

In contrast to serological or antibody detection tests, Ag detection tests depend heavily on the time of clinical onset and pathogenesis of the disease and the concentration of the pathogen in certain tissues and/or fluids. Successful diagnosis depends on appropriate timing and selection of the sampling site (affected tissue/lesions, scrapings, swabs, blood, and other body fluids), storage conditions *and specimen integrity during transport. For certain applications, the testing of individual animals and/or samples may be appropriate (e.g. confirmatory testing); while for other purposes (e.g. screening), pooling of animals may be efficient and effective. Selection of the appropriate specimen requires good understanding of the disease and the effect of the sample matrix on the pathogen (e.g. cloacal or tracheal swabs for avian influenza).*

Nucleic acid detection (NAD) tests are increasingly replacing classical antigen detection systems. For development and optimisation of NADs, please refer to Chapter 2.2.3. Although these NAD tests may seem to be the tests of choice for many applications, they are not always the most practical or efficient. In most cases it is still necessary and prudent, at least for an index case, to culture the agent on selective media or in susceptible cell lines or eggs to facilitate further characterisation and identification. While genotyping is an important consideration, especially in molecular epidemiology, other means of agent characterisation such as serotyping, pathotyping or biotyping are also important. Cultured and preserved agents have tremendous historical value and are also an important source of reference materials.

Due to its worldwide application, the Ag ELISA is used as an example for application of best practices in antigen detection assays in this chapter. Most of the basic processes used to validate other types of antigen detection assays will become evident by extension of those used to validate ELISAs. Because of the many conceptual similarities between antigen and antibody detection assays this chapter frequently cross-refers to Chapter 2.2.1 on antibody detection.

A. ANTIGEN DETECTION ASSAY DEVELOPMENT PATHWAY

1. Intended purpose(s) of the antigen assay

The intended purpose of the test is a key factor which will guide decisions in the selection and early development of the candidate assay. Given the WOAH-defined 'fitness for purpose' categories in Table 1, Ag detection systems may be appropriate for certain applications. Support for disease eradication or surveillance programmes generally require testing of high numbers of samples, with an emphasis on diagnostic sensitivity and throughput capacity. In contrast, confirmation of clinical cases does not entail high numbers to be tested, but diagnostic specificity and turn-around-times become very important. At the outset, the questions posed in the text box, above, should be carefully considered.

Table 1. Determinants of an antigen assay's fitness for its intended purpose

Assay characteristics	*Determinants of fitness for purpose*						
	*1**		*2**	*3**	*4**	*5**	*6**
	a	b					
Diagnostic sensitivity (DSe)		+++	+++	+++	+++		
Diagnostic specificity (DSp)		+	+	+	+++		
Positive predictive value (PPV)		+	+	+	+++		
Negative predictive value (NPV)		+++	+++	+++	+++		
Throughput capacity		+++	++	+	–		
Turn-around time of test		+	+	+	+++		

Assay characteristics	*Determinants of fitness for purpose*						
	*1**		*2**	*3**	*4**	*5**	*6**
	a	b					
QA capability		+++	+++	+++	+++		
Reproducibility		+++	+++	+++	+++		
Repeatability		+++	+++	+++	+++		

Other characteristics such as the technical sophistication of the assay, and the skill required for interpretation will be related to the disease or infection under investigation.
NB NAD tests may also be used for agent detection, and are considered in Chapter 2.2.3.
Symbols: +++ = essential; + = of less importance; – = not important.
*Basic purposes for which an assay may be deemed fit: 1. Contribute to the demonstration of freedom from infection in a defined population. 2. Certify freedom from infection or presence of the agent in individual animals or products for trade/movement purposes; 3. Contribute to the eradication of disease or elimination of infection from defined populations; 4. Confirmatory diagnosis of clinical cases (includes confirmation of positive screening test); 5. Estimate prevalence of infection or exposure to facilitate risk analysis; 6. Determine immune status in individual animals or populations (post-vaccination)

1.1. Purpose 1

For disease freedom categories as given in purpose (Table 1), antibody screening tests of high diagnostic sensitivity (DSe) are usually the tests of choice provided that a detectable immune response is a significant indicator of infection. However, there may be certain disease situations where the humoral immune response can be misleading and pathogen detection may be more appropriate (e.g. mycobacterial or trypanosomal infections). In these cases, Ag detection tests may be more effective. The antigen screening test should demonstrate a high DSe. Tests of high DSe demonstrate low false negative (FN) rates and when applied to low prevalence populations, the NPV is at its highest level. As DSe and diagnostic specificity (DSp) are usually inversely related, a decrease in DSp will result in an elevated false positive (FP) rate. Therefore, all screening test positive results should be subjected to some form of confirmatory testing to evaluate their true status. Confirmatory tests characteristically have high DSp and therefore a low FP rate. These tests are often more sophisticated and require enhanced interpretive skills.

1.2. Purpose 2

For a number of diseases included in the *Terrestrial Manual*, agent identification is listed as the preferred test method for the purpose of determining "Individual animal freedom from infection prior to movement". Although in many cases this involves culture of the organism or detection of nucleic acid, there may be situations where an antigen detection test is appropriate for this purpose. To avoid risk of disease spread through trade, a test offering high DSe is to be preferred.

1.3. Purpose 3

If the purpose of the test is the eradication of disease or elimination of infection from defined populations, antigen screening tests, like antibody screening tests, of moderate to high DSe, are the tests of choice. However, the rationale is slightly different in that the testing will likely be done at the herd or compartment level. At the beginning of the eradication campaign, when the disease prevalence is high, moderate DSe and DSp are suitable as both FP and FN rates are less relevant at this juncture and a moderate level of error is tolerable. Depending on the nature of the disease and rapidity of spread, high throughput and fast turn-around-times may become critical. Usually decisions are made without confirmatory testing at this point.

In the latter stages of the campaign, a higher DSe is warranted as the FN rate becomes the more critical factor. Much like Purpose 1, positive reactors will need to be subjected to some form of confirmatory testing to evaluate their true status. In these latter stages, antigen and/or nucleic acid detection systems are critical in the detection of sub-clinical cases, shedders and possibly, latent carriers.

1.4. Purpose 4

Although antibody tests of high DSp are often the tests of choice for confirmatory diagnosis of clinical cases, antibody tests may not always be the tests of choice, especially if clinical signs appear before an immune response is mounted. A prime example would be highly pathogenic avian influenza infections where mortality may occur before an immune response is even detectable. Antigen and/or nucleic acid detection tests are usually a better choice for confirmation of clinical cases provided that they offer a fast turn-around-time. In these cases, the idea is to maximise DSp and thereby minimise any potential FP reactions. For some clinical cases, e.g. vesicular diseases in terrestrial animals, several tests may be required to quickly rule out select pathogens that present similar clinical signs. In this category of test, fast turn-around-times are extremely critical in identifying potential outbreaks.

1.5. Purpose 5

For estimates of prevalence of infection and/or shedding to facilitate risk analysis, e.g. for health surveys, herd health status and to monitor disease control measures, antigen detection tests of moderate DSe and DSp are the tests of choice. In general, this would balance both FN and FP rates and result in a more accurate estimate of the true prevalence in the target population. However, if accurate estimates of both DSe and DSp have been established, statistical approaches can be used to minimise bias attributable to FN and FP rates (see Chapter 2.2.5 *Statistical approaches to validation*).

1.6. Purpose 6

Not applicable to antigen detection assays.

2. Assay development – experimentation

2.1. Reference materials, reagents and controls

2.1.1. Test samples

Samples required for antigen detection assays should be handled as described in Chapter 1.1.2 *Collection, submission and storage of diagnostic specimens*. Sample matrixes for antigen detection assays can be very heterogeneous (e.g. blood, faeces, milk, skin, semen, saliva, blisters, vesicles or swabs from affected tissues such as oropharynx (Probang), trachea, genitals, cloaca, oesophagus, etc.). The ideal specimen is the one that is easy to obtain and with a high concentration of the analyte. In many cases blood or swabs are the specimens of choice but depending on the pathogen, other tissues or fluids are needed, e.g. skin, organs such as brain (rabies, transmissible spongiform encephalopathies [TSE]), lymphatic organs, such as spleen and lymph nodes (classical swine fever), kidney, liver, heart, parts of respiratory tract (avian influenza), digestive tract (parvovirus), milk, faeces, semen, saliva, tumour material (enzootic bovine leukosis), etc.

As stated in Chapter 1.1.2, the usual considerations apply to limit bacterial and fungal contamination of specimens. The use of preservatives and fixatives is not usually recommended and samples should be sent with minimal delay and under refrigeration to a diagnostic laboratory. During transport and storage it is important to be aware of the physical and chemical requirements of the pathogen (e.g. foot and mouth disease [FMD] virus is highly labile at low pH and requires equal amounts of glycerol and phosphate buffer to maintain a pH over 7).

If samples are to be tested as pools, experiments need to be undertaken to demonstrate that the assay is fit for that purpose (e.g. that the analytical sensitivity is sufficiently high to detect one infected animal in a pool of 5, 10, 50 or more samples from uninfected animals).

2.1.2. Reference Standards

See Chapters 2.2.1 *Development and optimisation of antibody detection assays* and 2.2.6 *Selection and use of reference samples and panels*.

2.1.3. Positive and negative reference panels

Samples, containing concentrations of antigen over the intended operating range of the assay, should be used as controls during the development and standardisation of an antigen detection assay. They may be obtained from field specimens or produced in the laboratory as spiked samples (see Chapter 2.2.6). Negative samples should be obtained from known uninfected animals and this same matrix should be used when spiked samples are produced.

2.1.4. Purified and crude antigens for antibody production

In general, antigens to be used for the production of immunological reagents should be as natural as possible in terms of conformation to ensure that the presentation of epitopes mimics the orientation on the live organism. Therefore, isolation and/or purification methods used should preserve the antigenic integrity of the agent as much as possible.

For very large pathogens such as poxviruses, bacteria and protozoal parasites, protein microarrays may be useful to identify and select antigens which elicit strong immune responses.

2.1.5. Monoclonal and polyclonal antibodies for indirect antigen detection assays

Monoclonal antibodies demonstrate unique analytical specificities and are very useful in the detection of agent-specific epitopes at the group, strain or sub-strain levels. As such, they need to be considered carefully with respect to the application at hand and the desired specificity of the assay. Polyclonal antibodies, by nature, tend to demonstrate a broader range of specificities. Purified or semi-purified polyclonal antibodies are often the reagent of choice for trapping complex antigens because they usually demonstrate higher affinities than their monoclonal counterparts.

2.2. Design of test method

2.2.1. Choice of test

The prologue to a proper test design requires careful consideration of many variables in the context of performance requirements. The choice of assay must be coupled with its intended application, which usually necessitates consensus between the assay developer, statisticians, and other stakeholders such as epidemiologists and regulatory bodies. If the purpose is to develop a screening test (e.g. during a post-outbreak surveillance period) the emphasis will be on high DSe, high throughput, low cost, technical simplicity, low interpretative skill, etc. If the purpose is to develop a confirmatory test (e.g. for the confirmation of clinical cases or confirmation of positive screening test reactors), a different set of priorities will come into play including high DSp, fast turn-around-times, technical sophistication and interpretative skills. There are a growing number of point-of-care or pen-side tests that have their own set of additional robustness and ruggedness requirements given the variable conditions of the environment in which they will be used and the skill level of the operator who will performing and interpreting the test.

Aspects affecting choice of test

- Is the assay to be used for screening or confirmatory purposes, or both?
- Will the assay be used as a laboratory or field based test?
- Will it be used for one or more species? Which ones?
- Will the test be used for typing organisms to group, serotype or strain-specific levels?
- Will the test be applied nationally or internationally?

The antigen ELISA is conceptually the same method employed for the antibody ELISA (Chapter 2.2.1), with the exception that antigen is the targeted analyte, and antibodies are the primary reagents used for capture and detection of antigens. Depending on whether the antigen is adsorbed directly on the microplate or captured by antibodies on a solid phase, along with subsequent detection steps, different formats are available.

It is not always apparent which assay format should be used to best fit the intended purpose. Availability of reagents and the limit of detection of the assay for a particular application may be significant factors in limiting the choice. Since many of the systems now target highly specific antigens, the choice of antibody for both trapping and/or detection becomes critical.

Preparation of the test sample is also a critical consideration depending on the test format being used. The use of trapping or capture antibody in sandwich-type assays enhances selectivity and reduces potential matrix effects. For assays requiring direct application of the analyte to the solid phase, preparatory extraction, centrifugation or filtration methods may be necessary to remove extraneous material. For a more in depth discussion of these different assay formats, please see Crowther (2001).

Of critical importance is the size and complexity of antigen and the availability of relevant reagents, such as capture antibodies (e.g. antigens to be detected in sandwich assays must have at least two unfettered epitopes) which limits this assay type to relatively large antigens or whole pathogens. The affinities of the immunological reagents come into play as the stability of the resulting antibody-antigen complexes in the microplate or on beads will affect the performance characteristics of the assay.

Practical concerns are availability and use of antigen standards for quality control and assurance purposes, repeatability, reproducibility, throughput capacity, turn-around-time of a test result, cost and technical sophistication and interpretation skills.

Working with exotic and/or zoonotic agents requires particular attention to biosafety and biosecurity regulations (see also Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*).

2.3. Proof of concept experiments (feasibility studies)

The same types of experiments used in antibody detection tests are required for antigen detection tests (see Chapter 2.2.1).

2.4. Samples and data expression

2.4.1. Selection, storage and use of control samples for test development and validation studies

It is important to assess and monitor sensitivity and specificity of the test during development and validation. This is achieved by selecting several samples (4–5 is adequate) that range from negative to high levels of antigen of the analyte in question. These samples are used in experiments designed to optimise the assay. To achieve continuity of evidence requires care and forethought in preparation and storage of samples. A large volume (e.g. 10 ml) of each control sample is acquired and divided into 0.1 ml aliquots for storage at or below –80°C. One aliquot of each sample is thawed, used for experiments, and ideally then discarded. If it is impractical to discard the aliquot, it may be held at 4°C between experiments for up to about 2 weeks; however, there is a possibility of sample deterioration under these circumstances. Then, another aliquot is thawed for further experimentation. This method provides the same source of sample with the same number of freeze–thaw cycles for all experiments (repeated freezing and thawing of samples can denature antigen and/or facilitates the growth of other unwanted microorganisms and should be avoided). Also, variation is reduced when the experimenter uses the same source of sample for all experiments rather than switching among various samples between experiments. This approach has the added advantage of generating a data trail for the repeatedly run samples. After the initial stages of assay validation are completed, one or more of the samples can become reference reagent(s) that are the basis for data expression and repeatability assessments both within and between runs of the assay (Jacobson, 1998). They may also serve as in-house working standards if their activity has been predetermined; such standards provide assurance that runs of the assay are producing accurate data (Wright, 1998).

2.4.2. Normalisation of results and their expression

The same normalisation procedures as used for antibody detection assays are applicable to antigen detection assays (see Chapter 2.2.1 for details).

2.5. Optimisation

The aim of this stage is to finalise test parameters related to reagents, consumables and equipment that will lead to a fixed protocol and will be used during the assay validation pathway Part B. For details, see Chapter 2.2.1.

Optimisation and standardisation

- Is the test able to distinguish between samples with and without the analyte (what is the limit of detection = analytical sensitivity?)
- Does the test cross-react with non-target antigen in the sample or sample matrix (analytical specificity)?
- What is the noise or background activity in a negative sample?
- Has the repeatability been assessed for a range of control samples over a number of days
- Are sufficient positive and negative samples on hand to carry out the experiments for optimisation and validation
- If yes, are reference and control samples dispensed and stored properly to avoid introduction of sample related bias (sample deterioration)?
- Have all critical reagents been run against each other in checker board titrations?
- Did you find optimal concentration/dilutions for each reagent?
- Did you include reference reagents and working standards/controls and did you normalise the OD data to achieve the best possible comparative results?

2.6. Inhibitory factors in sample matrix

Due to a higher variety and complexity of specimens, antigen detection assays are more likely to be influenced by matrix factors than antibody detection assays, which normally detect antibodies in serum. Inhibitory substances are frequently found in complex matrixes such as pus, semen, tracheal/nasal/cloacal swabs and may have an impact on the test result. ELISA antigen detection systems are rather resistant to inhibitory factors, please see the WOAH Validation Standard, Section A.2.4, and Greiner *et al.* (1997) for descriptions of the type of inhibitors that could affect the assay. These references should be reviewed carefully to assure that all inhibitory factors are accounted for and controlled.

2.7. Calibration to reference sample and comparison to standard test method

Chapter 2.2.1 contains information relevant to this procedure.

B. ASSAY VALIDATION PATHWAY

1. Stage 1 – Analytical performance characteristics

1.1. Repeatability

Chapter 2.2.1.

1.2. Analytical specificity

Analytical specificity (ASp) is defined as the degree to which the assay distinguishes between the target analyte and other components that may be detected in the sample matrix (see Chapter 2.2.6, Section B.1). The higher the ASp, the lower the number of false positive results. ASp should be determined by testing well characterised samples from similar or related pathogens, which produce similar lesions as the target pathogen or are frequently found in samples containing the target pathogen. For example, to assess the ASp of a

Analytical performance characteristics

- Has repeatability been established for a range of positive and negative samples within and between runs of the assay?
- Have upper and lower control limits of the assay been established?
- Have you defined ASe and ASp for this assay?
- Does the candidate assay compare favourably with a standard test method, based on objective quantitative and qualitative criteria?

FMD antigen detection ELISA for one particular serotype (e.g. serotype O), it is necessary to assess its reactivity of all sub-strains within this serotype (e.g. O Campos, O Manisa, etc.) to assess inclusivity. At the same time it is important to show that the test does not cross-react with other serotypes such as A, Asia 1, C, SAT 1, 2 and 3. Finally, there is also a need to assess whether the test cross-reacts with agents from diseases which may produce similar signs, e.g. vesicular stomatitis, swine vesicular disease and swine vesicular exanthema. Another example is an ELISA designed to detect avian influenza virus: as a screening test the assay should detect the nucleoprotein or matrix antigen of all subtypes, e.g. H1-H16 and N1-N9. However it should not cross-react with viruses which cause similar clinical signs such as Newcastle disease or infectious bursal disease (diagnostic specificity) or with other non-specific components present in the matrix or on the solid phase. Some ELISAs may be subject to false positive results attributable to non-specific factors, such as non-specific binding of antibody conjugates to the plastic surface and may require use of blocking agents. Care must be taken to eliminate these types of errors.

1.3. Analytical sensitivity

Analytical sensitivity (ASe) is synonymous with the lower limit of detection (LOD) of antigen concentration in a sample. LODs are usually determined by endpoint dilution in which replicates (preferably 10) of each dilution in a $\log_2$ dilution series are run in the assay. The larger the number of replicates, the more precise the determination of the dilution at which the antigen is no longer detectable. Further information on LODs and ASe is given in the WOAH Validation Standard and in Chapter 2.2.5.

Screening assays or assays which are designed to detect sub-clinical infections or carriers should have a very high ASe. In these cases it may be difficult to obtain suitable samples and to determine the comparative ASe by running a panel of samples on the candidate assay and on another independent assay. If available, serial samples from experimentally infected animals could provide temporal information about the assay's capacity to detect antigen over the course of infection.

1.4. Standard test method comparison with the candidate test method

Chapter 2.2.1.

2. Stage 2 – Diagnostic performance characteristics

See also Chapter 2.2.1.

2.1. The challenge in establishing accurate estimates of DSe and DSp for antigen assays

For all antigen detection assays including ELISAs, particular consideration must be given to the timing when the sample is taken as the probability of detecting antigen or the pathogen itself is very closely linked to the stage of infection. The diagnostic window will likely be much smaller in antigen/pathogen detection assays than in antibody detection tests as immune responses can normally be measured over an extended period of time. Dynamics of infection, e.g. acute, persistent, sub-acute, chronic or carrier-state are important determinants for sampling recommendations. For example, during an acute viral infection, the sample should be taken as early as possible after the onset of clinical signs. In persistent, sub-acute, chronic or carrier animals there is a balanced relation between the pathogen and the host and the agent may be present in minute concentrations which may be very difficult to detect. During the course of pathogenesis, other organ systems may become involved and different tissues or fluids may be more appropriate target tissues for sampling as the disease progresses.

Diagnostic performance characteristics

- Are the criteria used to determine the positive and negative reference populations legitimate?
- Do the reference samples fully represent the population targeted by the assay?
- Were there difficulties in obtaining a sufficient number of samples? If so, how was the problem addressed?

2.2. Reference animal populations

2.2.1. Animals of "known infection status"

Depending on the composition of positive and negative reference samples, the same test may have different estimates for DSe and DSp. Ideally the composition of reference samples and animals should match as closely as possible the samples which are expected from the target population for which the test was developed. It is important to have a clear case definition. This is a set of criteria used to decide whether an individual or group of animals is infected or not. The reference status must relate to the purpose of the testing. For example, if the purpose of the assay is to be used as a screening test to detect early infection of FMD (e.g. in free-ranging cattle with vesicles), then the majority of samples to determine DSe and DSp should be taken from this target population. Relevant information should be collected and summarised for all animals involved at this stage of validation (e.g. species, age, sex, breed), and information on other factors that are known to influence DSe and DSp (e.g. date and place of sampling, immunological status, vaccination and disease history, pathognomonic and surrogate tests used to define status of animals, prevalence within population and description how the reference status was derived).

A sample from a negative reference animal refers to lack of exposure to or infection with the agent in question. For example a classical swine fever negative population could be defined as a region with pig herds without confirmed clinical cases of the disease in recent years, supported by negative serological tests and negative virological test results of suspected cases. Samples from these animals fulfil the status of negative reference samples. The negative reference population should be chosen with care so as to ensure that it is representative and matches the positive reference population (e.g. as to the breed and exposure to environmental challenge).

If vaccination is carried out, it may interfere with antigen detection (e.g. vaccination with modified live viral vaccines). Samples from these animals should not qualify as negative reference samples.

The types and limitations of reference standards commonly used for evaluation of the performance characteristics of a new assay are listed here. An expanded description of each reference standard is provided in Chapter 2.2.1, Section B.2.2.1 and in Jacobson, 1998. The strengths and limitations of these reference standards must be considered carefully when using samples, derived from animals that fall into any of the following four categories, as sources for establishing DSe and DSp for a candidate assay (Jacobson, 1998).

i) An unequivocal reference standard

   An unequivocal reference standard: presence of the agent in the host or evidence of definitive (pathognomonic) histopathology.

ii) A composite reference standard

   A composite reference standard: verification of uninfected or unexposed animals.

iii) A relative reference standard

   A relative reference standard: reference animals that have been classified for their infection status by comparison with the test results of another assay for antigen or nucleic acid detection on the same samples. As with antibody assays, the estimates of DSe and DSp are useful only insofar as the reference test has documented, established and acceptable performance characteristics. A deficiency of relative reference standards is that they have their own established levels of FP and FN test results, which are sources of error that will be compounded in estimates of DSe and DSp for the new assay. Generally, however, the use of other well described test methods is regarded as good practice to determine the status of reference animals, but only if the inherent bias introduced by the relative reference standard is accounted for.

iv) An adjunct reference standard: experimental infection or vaccination

See the WOAH Validation Standard, Section B.2.3 for significant limitations of this type of standard. Note: In the context of antigen detection, "comparative" tests should include pathogen detection by isolation, culture, NAD tests or histopathology or other *in-situ* techniques.

2.2.2. Latent-class models for sample selection

For a discussion of this approach to sample selection, see the WOAH Validation Standard, Section B.2.5 and Chapter 2.2.6.

2.3. Threshold (cut-off) determination

It is important to clearly describe the method and the samples used for selecting a cut-off. It is strongly recommended to conduct a receiver operating characteristic (ROC) analysis to show the potential performance of the test in other epidemiological settings.

3. Stage 3 – Reproducibility and augmented repeatability estimates

Reproducibility assessments for antigen detection assays are not uniquely different from similar assessments for any other type of assay. Therefore the reader is directed to the WOAH Validation Standard, Section 3, for details on reproducibility analysis and for reference samples and panels to Chapter 2.2.6. WOAH provides guidelines for laboratory proficiency testing (https://www.woah.org/en/what-we-offer/expertise-network/reference-laboratories/#ui-id-5).

4. Stage 4 – Programme implementation

4.1. Interpretation of results

See the Chapter 2.2.1, Section B.4.1.

5. Monitoring assay performance

5.1. Monitoring the assay

After performance characteristics of the new test have been established, on-going monitoring, maintenance and enhancement are required. It is important to continue monitoring the repeatability and reproducibility of the assay over time, on a per run basis, quality control samples have to fall within pre-established limits. If not, the test result is not valid and has to be repeated. Monitoring the assay controls' performance over time is an important way to detect changes or trends in the assay. Simple analysis of results, e.g. statistical assessment of mean values, standard deviation and coefficient of variation are useful in this process and results can be plotted in a control chart. Participation in external quality control or proficiency testing programs is useful to identify random and systematic errors and provide credibility in test results. Further information about this topic can be obtained from Crowther *et al.* (2006) and in the Chapter 2.2.1, Section B.5.1.

5.2. Minor modifications of the assay – replacement of depleted reagents

Over time changes in the test protocol may be necessary due to better or less costly reagents or because the target analyte has changed. Batch-to-batch variation of biological reagents is considered a major contributor to test variation. When reagents such as antibodies or antigen must be replaced they should be produced or procured using the same protocols or criteria as used for the original reagents. New biological reagents (e.g. control samples, antigen, capture or detection antibodies, conjugate, chemicals or consumables) need to be assessed for comparability. Chapter 2.2.8 *Comparability of assays after changes in a validated test method* gives an overview of acceptable comparability studies. A ground rule is never to change more than one reagent at a time in order to avoid the compound problem of evaluating more than one variable concurrently (see also Chapter 2.2.1, Section B.5.2).

5.3. Major modifications of the assay – changing to a new ELISA type

It is a major challenge of laboratory diagnosis to keep up with the evolving nature of infectious pathogens. Over time pathogens may change their antigenic characteristics and new strains may emerge, e.g. the emergence of Bluetongue virus serotype 8 in northern Europe in 2009. This change necessitates a full test development and validation study. Another major change is the use of a test in a different species than that for which it was originally validated, e.g. there may be a requirement to use an FMD Ag detection ELISA, validated in cattle, for testing camelids or buffalo in different geographical and climatic regions. Evaluation of reference samples that represent those populations of Stage 2 in Figure 1 of the WOAH Validation Standard will accomplish this requirement (see also Chapter 2.2.1, Section B.5.3).

5.4. Enhancing confidence in validation criteria

Due to the extensive set of variables that have an impact on the performance of antigen detection assays, it is useful to expand the number of reference samples when possible, due to the principle that error is reduced with increasing sample size (see also Chapter 2.2.1, Section B.5.4).

CHAPTER 2.2.3.

DEVELOPMENT AND OPTIMISATION OF NUCLEIC ACID DETECTION ASSAYS

INTRODUCTION

The WOAH Validation Recommendations in Section 2.2 Validation of diagnostic tests *of this* Terrestrial Manual *provide detailed information and examples in support of the WOAH Validation Standard that is published as Chapter 1.1.6* Validation of diagnostic assays for infectious diseases of terrestrial animals*. The Term "WOAH Validation Standard" in this chapter should be taken as referring to that chapter.*

An ever increasing number of nucleic acid detection (*NAD*) *tests are now being used for diagnosis of infectious diseases in various species of animals and man. The most common methods are the polymerase chain reaction* (*PCR*), *of which there are a number of variations and isothermal amplification methods* (*such as loop-mediated isothermal amplification*)*. In addition, solid-phase or liquid phase microarrays are appearing as new tools of biotechnology-based diagnosis. The amplification techniques employed in these assays provide them with high analytical sensitivity. The products of the amplification reaction can be detected in a number of ways, for example, by visualisation in agarose gels, using labelled probes* (*e.g. TaqMan probes*), *by the detection of the accumulation of the products in real time or by using arrays where specific probes are captured on a solid-surface matrix or on beads* (*Lauerman, 2004; Viljoen* et al., *2005*)*. Different PCR assays can be multiplexed together to detect several targets in one tube or to combine targeted analytes and controls that generate different amplification products, all in one reaction vessel. Whilst this has obvious advantages, great care must be taken during optimisation to ensure that assay performance is not compromised. Similarly a multiple outcome PCR can be created using one set of primers, but employing tagged probes, which bind to different target sequences in the different species or strains detected by the PCR* (*Wakeley* et al., *2005; 2006*).

NAD amplification techniques are usually based upon the principle that there is an exponential amplification of the specific sequence targeted in the reaction. This provides a NAD with high analytical sensitivity and specificity. Due to this characteristic high level of sensitivity reached with NAD, special care, and indeed special precautionary steps have to be taken to prevent NAD amplicon contamination to subsequent sample analyses. This is more likely to be a problem where reaction tubes are opened in the laboratory for further processing, for example, to run gels or to perform nested assays. To avoid such contamination, strict laboratory protocols should be employed involving separate rooms or cabinets for particular stages of the assays, changes of laboratory gowns and gloves, and stringent cleaning programmes (*Viljoen* et al., *2005; Subcommittee of Animal Health Laboratory Standards*)*. For these reasons, tests based on closed tube systems are generally more suitable for diagnostic assays* (*Sawyer* et al., *2006*). *As with all assays, it is important to use appropriate controls to prove that the assay is performing as expected. All samples used in assay development should have well established provenance and the development should be carried out within the framework of a quality system to ensure appropriate levels of training, equipment maintenance and monitoring, etc.* (*Burkhardt, 2000*).

A. ASSAY DEVELOPMENT PATHWAY

1. Definition of the intended purpose(s) for an assay

Purpose of the assay:

- Is it for a screening or confirmatory test, or both?
- Is it for detection of a group of pathogens?
- Is it for detecting a single disease agent?
- Is it for discriminating between vaccinated and infected animals?

The first consideration in assay development is to define clearly the specific purpose and application of the test to be developed and to understand how it will be applied because this informs many of the decisions of the development pathway. For example one might choose to develop a screening test to detect all avian influenza (AI) subtypes or variants in birds for which an inclusive and broadly reactive test is necessary, or to determine the haemagglutinin type, in which case a more specific test is needed. For some tests the requirement is to detect a group of viruses, e.g. the pan-pestivirus PCR that detects bovine viral diarrhoea (BVD), border disease (BD) and classical swine fever (CSF) viruses. For other tests, the requirement may be to detect a single agent, or sometimes even to allow a DIVA (differentiating infected from vaccinated animals) approach. An example of such a method is the recently published real-time RT PCR assay for CSF virus which was developed for the genetic differentiation of naturally infected from vaccinated wild boar (Liu *et al.,* 2009).

2. Assay development – experimentation

2.1. Quality assurance

It is important that assays are developed in laboratories where high standards of quality assurance and control are employed (see Chapter 1.1.5 *Quality management in veterinary testing laboratories*). The validation data for test performance and accuracy determined during the development and validation phase must be robust as it will form the basis for interpretation of disease status and consequent actions when the assay is routinely used.

2.2. Reference materials

Sample selection (see Chapter 1.1.2 *Collection, submission and storage of diagnostic specimens*).

- What kinds of samples will be used from the target population?
- What are the predilection sites for the agent in the host?
- What sample collection, storage and transport methods are anticipated and what are the possible effects on results?
- Will samples be single or pooled?
- Will samples in the validation panel be representative of the target population?

For most diseases, the samples required for NAD assays are likely to be similar to those used for current detection methods such as bacterial cultivation or virus isolation. For example, detection of AI by real-time RT-PCR and virus isolation use the same samples. Recently, swabbing of fresh cuts in organ samples proved to be a practical approach, replacing the laborious homogenisation of organ samples. Similarly, there is a trend to use samples, which can be obtained by non-invasive methods, such as saliva for detection of porcine reproductive and respiratory syndrome (PRRS) in pigs (Prickett *et al.,* 2008) or bulk milk samples for determination of herd BVD status. Prior to the selection of pooled samples, such as bulk milk, test developers need to consider and assess the implications of dilution of the target analyte on diagnostic sensitivity and incorporate this into the validation plan (see below).

It is important to understand the biology of the pathogen concerned and the nature of the sample collection devices. As in the case of AI, different subtypes or variants of the viruses have different predilection sites in host birds. For example cloacal samples are appropriate for some subtypes, whereas buccal samples are acceptable for others. Therefore, a test for use in a surveillance programme would need to incorporate both sampling sites and be validated using both types of sample. Another significant factor is the matrix in which the analyte resides in the host. Cloacal samples are more likely to contain PCR inhibitors than buccal samples. Another potential confounding factor is

the type of swab used to collect the samples; some contain materials that inhibit PCR assays. Therefore, it is very important to specify precisely the preferred sample material and to describe fully the swabs and swabbing protocol, including the preferred buffers or transport media and storage conditions.

Consideration also should be given to whether samples should be tested singly or in pools and whether pools should be of different samples from a single or multiple animals. Any pooling strategy should be precisely defined and validated prior to use. Finally, if the target population is "birds", the validation study should cover a large representative population of different species to demonstrate that the assay is widely applicable, whilst concentrating on the most prevalent species or those used as sentinels of infection.

2.3. Design of test method (fitness for purposes)

2.3.1. Choice of test

For most surveillance activities large numbers of samples may be tested first by a screening assay. In the above example for AI, the screening assay described must detect all known subtypes or variants of Influenza A, either in a particular region or throughout the world. The test must be highly sensitive so it does not miss true positive samples, and analytically specific (inclusive) for detection of all viruses in the Influenza A group.

Avian Influenza is a high profile disease. If a new test should generate a high proportion of false positive results that cannot otherwise be confirmed, the infection status of the birds would be difficult to resolve. Exclusion of closely related agents that are not of interest within the context of the intended purpose of the assay is therefore essential.

- Is the test for use only in a particular region or world-wide?
- Is it sufficiently sensitive and is the analytical target inclusive enough to not miss positive samples?
- Consider the impact of a high proportion of false positive results that cannot be confirmed
- Are rapid results possible and/or necessary?
- Will confirmatory tests (an analytical tool) be used to determine/confirm pathogen pathotype (strain)?
- Will determination of the strain have important bearing on the action taken?

To continue with the AI screening example, it is also important for the test to produce rapid results so that disease control measures can be swiftly applied. So, for the detection of avian influenza, the logical choice of tests would be a real time PCR using TaqMan probes or a field based assay. For an AI screening assay, the primers and probes are likely to be based upon the Matrix (M) gene which is known to be present in all influenza type A isolates. Dependent on the assigned fitness for purpose, the scientists may choose to develop an additional assay for use in conjunction with the screening test to determine which particular strain of AI is present and whether the strain is highly pathogenic, because this has an important bearing on the notification requirements and control measures that may follow. Some test methods may qualify as secondary analytic tools that are applied to the analyte detected in the primary assays, and may be used to further characterise the product detected in the screening assay (see the WOAH Validation Standard, Section B.1.4). An example of such an analytic method would include sequence analysis of the matrix PCR amplicon detected during AI screening. Development of paired confirmatory assays such as real-time PCR assays that target other genes, such as the AI haemagglutinin or neuramindase to identify subtype or pathotype, would require that those assays also undergo all steps of development, optimisation and validation. Recently a novel, plexus-primers-cased PCR assay was developed at the WOAH Collaborating Centre for the Biotechnology-based Diagnosis of Infectious Diseases in Uppsala, Sweden. This assay allows the simple and rapid determination of various RNA-virus pathotypes. For example, avian influenza viruses and Newcastle disease viruses can be detected and evaluated with low-cost equipment (PCR machine) and in a very short period of time (less than three hours), in simply equipped laboratories or even on site, in the field, during outbreak situations (Leijon *et al*., 2011; Yacoub *et al.,* 2012). This indicates a very rapid development and simplification in the field of NAD tests in diagnostics towards field/on-site applications.

2.3.2. Method design

The method should be carefully designed to fulfil the purpose that was defined at the outset. Important factors to consider will include application, types, and numbers of samples to be tested. This, in turn, leads to logistical and practical considerations for the candidate assay, such as whether it will be conducted in a laboratory, with or without automation to achieve high throughput, or in the field using a pen-side assay. All available information such as publications, sequences deposited in databases and in house sequence data should be used. Sophisticated software is available to optimise primer and probe design; computer modelling of probable sequences for use in the assay is a first step.

- Was the assay first evaluated on a small sample panel (six to eight samples) to assess viability of the approach?
- Was there good separation between test results of negative and positive samples?
- Was a preliminary test made on a dilution series in matrix to assess preliminary relative analytical sensitivity?

2.4. Feasibility study

Before embarking on the validation of a newly developed prototype assay, a feasibility study should be carried out using a small panel of approximately six or eight well-characterised samples to assess whether the system is viable. The panel should consist of samples distributed across the operating range of the assay, i.e. at least two negatives, at least two unambiguous positives, and ideally samples falling mid-range. Ideally these samples should come from different animals. The assay should achieve as wide-as-possible separation of test results for the high positive and negative samples in this panel. It may be useful to test a dilution series (analyte diluted in matrix) at this point to assess relative analytical sensitivity if the test is a potential replacement for another method where sensitivity is an important criterion (see Chapter 2.2.8 *Comparability of assays after changes in a validated test method*).

2.5. Development and optimisation

- Optimal location? Use a clean room or cabinet system to minimise contamination
- Optimal method of sample extraction to prepare samples? Done manually or by automation?

The aim of this stage is to define and optimise the method that will be used to carry out the test in future routine testing. This includes description of appropriate facilities to carry out the assay. It is important to consider both the method of sample extraction required to prepare samples for the test and the assay procedure. For any PCR assay, definition of clean room protocols is required to minimise contamination. If large numbers of samples are anticipated, selection of an automated extraction procedure may be essential (Jungkind, 2001).

Usually, it is necessary to assess a number of different test methodologies and vary concentrations of reagents, template additions and reaction times to optimise the extraction and the assay. It is important to either change only one variable at a time or use a multi-factorial design and analysis (see the WOAH Validation Standard, Section A.2.5 on Robustness). It is important to identify which factors have only a narrow range of optimal activity, as these are critical points in the assay procedure and may affect an assay's robustness. Generally, the assay stages are relatively simple to optimise, but care needs to be taken to ensure a robust nucleic acid extraction, and that all assay reagents, and procedural steps are optimised and suitable for routine laboratory application (Burkhardt, 2000).

- Have concentrations of reagents been tested for optimal reactivity?
- Has extraction been optimised?
- What are the template additions and reaction times to optimise the assay?
- Which factors have a narrow range in which they perform optimally?
  - Has that range been defined?

Controls for PCR are many and varied. It is important to include appropriate controls to show that the assay is performing as expected. The various controls that should be considered include:

2.5.1. A host-species control

This control demonstrates that the target species has been appropriately sampled. In the AI screening assay example, the control verifies that the sample swab had been in contact with a target species and that the sample contained "bird" nucleic acid, which is available for extraction using the defined protocol. A possible target for this control is a housekeeping gene such as beta actin, which is present in the target host species. This is relatively simple if the host species is a single species e.g. chickens, but it will be more challenging to find a suitable target for all "bird" samples. This type of control may not be required if a sample is added directly to the extraction process, such as a piece of tissue or blood, but is recommended for "indirect" samples such as those collected on swabs; in this case, the host-species control should be used for every sample tested.

Have you included all necessary controls to prove the assay is performing as expected?

- Template control?
- Inhibition control?
- Positive sample control?
- For RNA assay – reverse transcription control?

2.5.2. No-template control

This control reveals whether contamination of the sample has occurred, resulting in amplified product when no amplified product should be present, as in a sample containing no target. Consideration should be given to the number and placement of no template controls in the assay set up template. Generally, a number (approximately 5% of wells) of no-template controls are distributed randomly within the assay or over the plate when 96 and 386 well-plate formats are used.

2.5.3. Analyte-positive control

This positive control, having a real-time PCR cycle threshold (Ct) activity within the defined operating range of the assay, is used on each plate. A suitable choice for this control may be a plasmid containing the target sequence, which can be used to check for the expected level of amplification in the assay. However, this does not assess the efficacy of the extraction process, which requires a known field sample or its equivalent (such as a sample from an experimental infection).

2.5.4. Inhibition control

- Have both the advantages and disadvantages of including an internal control been considered?
- Is the purpose and application of the inhibition control clearly specified in the assay protocol?

This control is needed to detect possible inhibitors of the PCR reaction. If an inhibition control yields a negative result, this infers that the sample contains inhibitory substances and that a negative test result for the test sample cannot be interpreted as "negative" because the assay did not perform correctly. Certain samples such as faeces and semen often contain inhibitors whereas this may be less of a problem when testing blood samples or cultured organisms (Ballagi-Pordány & Belák, 1996). Data collected during the validation process concerning assay performance using the sample matrices being targeted will allow for a risk-based decision as to whether an inhibition control should be included for each sample or whether the test system is unlikely to be affected by inhibition. If inhibitory substances are a significant problem an inhibition control must be included for each test sample.

There is considerable debate about the most suitable and effective inhibition control. Examples include the following:

i) An artificial target, such as a length of DNA contained in a plasmid, which is added to the extracted sample and amplified with the same primers as the test target, but is of a different size or contains a different internal sequence so that it is identified as the internal control when the detection method is applied (Sawyer *et al.,* 2006).The advantage of this approach is that it utilises the same primers employed in the test, and the control can be added at precise concentrations. Because the target for the assay and for the control is the

same, competition for the primer and dNTPs may reduce the analytic performance of the assay. Care must be taken during assay optimisation, so that the analytical sensitivity of the assay is not detrimentally affected. Another disadvantage is that as an added component, this control only verifies the assay stage of the test and does not act as a control for the extraction stage.

ii) An alternative strategy for an inhibition control is to amplify a housekeeping or structural gene such as β-actin which always is present in the target tissue, and thus the sample. If the housekeeping gene has been inhibited by substances in the sample, the inference is that amplification of the gene targeted by the test may also be inhibited. This conclusion is not always warranted. Housekeeping genes are often present in abundance, so sometimes can be detected even in the presence of inhibitory substances while the more limited amounts of the assay's targeted sequences may be inhibited from amplification. In this case, the amplified and detected housekeeping gene was not a sufficient control for inhibitors, resulting in significant risk of a false negative inference for the test result. However, with knowledge of the risk associated with housekeeping genes, which are naturally present in the sample housekeeping genes can be a useful control for inhibitors for the whole assay including sampling, storage and extraction.

2.6. Inhibitory factors in the sample matrix

Generally for NAD methods, pure cultures, blood and most tissues are the preferred samples because extraction and recovery of amplifiable NA is generally successful. Faecal samples, semen and autolysed tissue can be more challenging because they generally contain more inhibitors for NAD assays. It is vital to have a robust and repeatable sample extraction procedure, which is appropriate for the numbers of samples to be handled (automated if necessary) and to utilise inhibition controls as necessary (see section above).

2.7. Operating range of the assay

- For determining the operating range of the assay, were samples diluted in the matrix for which the test is intended?
- Does the operating range of the assay conform with the expected norms for such an assay?

The operating range of the assay should be determined by diluting a strong positive sample and plotting the range of results obtained versus known amounts of nucleic acid (concentration, dilution, number of genomic copies, etc.). This reference sample must be in the same matrix as the test sample, i.e. it is not appropriate to determine the operating range of a sample diluted out in buffer, if the usual matrix is blood.

2.8. Robustness

An assay should tolerate small changes in concentrations of reagents and/or slight variations in processing times and temperatures used for different stages of the assay in order to be effectively deployed and provide reproducible results when used in multiple laboratories. This can be determined during assay optimisation when critical procedural steps, reagents, and equipment are identified. Such factors that when not adhered to cause unacceptable variability should be well described in the assay protocol so that particularly exacting processes are assured for carrying them out. This is a laborious process that ultimately is monitored for precision and accuracy by internal and external quality control samples run in the assay.

2.9. Calibration of the assay to reference samples

- Have you calibrated the assay to external reference standards?
- If external reference standards not available, have you created an in-house reference standard?
- Have you made working reference standards in sufficient amounts for use in all development and validation experiments?

Ideally, international or national reference standards should be used to calibrate the assay. However, these are not always available so it may be necessary to create an in-house reference standard (see Chapter 2.2.6 *Selection and use of reference samples and panels*). A working standard(s), for inclusion in all runs of the assay, needs to be created, aliquotted, and stored in sufficient quantities for use in every run of

the validation process and for routine use after the validation has been completed. The working standard(s) could be multiple aliquots of a particular sample, which can be used within each assay run. They could also consist of a plasmid containing the sequence of interest, spiked into sample matrix. Use of the latter allows the test developer to determine the number of genome copies that can be detected by the assay. In some instances test sample results are "normalised" by comparison to the working standard sample(s) included in each run of the assay. This allows direct comparison of data between runs (Huggett *et al.,* 2005; and WOAH Validation Standard).

B. ASSAY VALIDATION PATHWAY

Once the protocol for the assay has been developed and optimised, it must be fixed and held constant while being evaluated through the stages of the validation pathway and during routine use. Minor changes to a validated assay can be addressed using comparison studies to document that the assay continues to perform as originally defined (see Chapter 2.2.8).

1. Stage 1 – Analytical performance criteria

1.1. Repeatability (Ct or qualitative conventional PCR)

- Has intra- and inter-assay repeatability been determined?
- Is repeatability within the accepted range of coefficient of variation (CV) limits?

Repeatability of the assay is a measure of agreement between results (within and between runs) using the same test method in one laboratory. Usually a small panel of three (preferably five) samples covering the operating range of the assay is selected and tested using the entire assay procedure (including nucleic acid extraction). Within assay (intra-assay) variation is determined using multiple (at least five) replicates of each sample in this panel in one assay run. Between run (inter-assay) variations are determined by testing these samples over several days, using several operators and at least 20 runs. The repeatability panel should be tested treating all samples and each of their replicates exactly like individual diagnostic samples, subjected to every step from sample preparation to data analysis. Accordingly, every replicate of every sample is subjected to an independent extraction. This allows for determination of repeatability, both within and between runs of the assay that mimic future runs of the assay when implemented for diagnostic use. Minimal variation in repeatability is important, particularly near the cut-off(s) that establish positive, inconclusive and negative ranges, because higher variability can result in incorrect interpretations (see Chapter 2.2.4 *Measurement uncertainty*).

Repeatability can be expressed as a coefficient of variation (see Chapter 2.2.5 *Statistical approaches to validation*). The assay should be designed so that the decision point (cut-off) lies on the steepest part of the real-time PCR Ct curve. If this is achieved, repeatability will be optimal at the critical point of the assay. (Larger CVs at the clearly negative and highly positive ends of the operating range of the assay do occur and have little impact on test result interpretation).

1.2. Analytical specificity (ASp)

Depending upon the intended purpose of an assay, its analytical specificity is determined by the selected genetic sequence(s) of organism(s) targeted by the assay. The assay can be designed to be highly selective, with analytically specificity for a single genetic sequence that is not known to be present in other organisms or strains of the targeted organism. Such an assay is said to exhibit exclusivity and connotes a confirmatory assay of high ASp.

Alternatively, the assay may be designed to target a conserved genetic sequence that is common to several strains of a given species, or several species of a genus. Such an assay has an ASp that exhibits inclusivity, making it useful as a screening test. For an inclusive screening assay, the analytical specificity should be determined by testing all lineages, strains, species, etc., that the assay is expected to detect. The assay should then be evaluated for its capacity to exclude related organisms such as non-pathogenic strains that are not of interest to the intended purpose of the candidate assay.

In the example of an AI screening test, the assay should be evaluated against as many well-characterised isolates of AI virus as are available to assure that all strains from a variety of geographical areas and hosts are detected (i.e. to demonstrate inclusivity). This is generally done using laboratory strains/cultures or extracted nucleic acid. For AI, different lineages of the virus exist such as Asian, European and North American. It is important to consider how the assay will be used and in which geographical regions. That will aid in determining whether it is necessary to evaluate some or all of these lineages. This important requirement is clearly demonstrated with the recently developed rapid and simple RNA-virus pathotyping assays, which were tested on a large collection of AI and Newcastle disease viruses, originating both from the Eastern and from the Western hemispheres (Leijon *et al.,* 2011; Yacoub *et al.,* 2012), in a collaboration between various WOAH Collaborating Centres. Another important factor is that viruses can change rapidly and the resultant mutations can render a diagnostic test sub-optimal. An example of this is the appearance of the 2009 pandemic strain of Influenza A H1N1 and the 2013 low pathogenic AI H7N9 outbreak in Southern China. The analytical sensitivity of the PCR for the traditional M gene was impaired for this strain because the sequence that rendered the assay specific had mutated. In most countries new primers have been introduced and used either as a new test or in combination with the traditional M gene primers as a combination test.

- Has a panel of as many well-characterised isolates of the target pathogen as possible, including isolates from a variety of geographical areas and hosts, been tested?
- Have related organisms and pathogens, which cause similar clinical syndromes, been tested?

The discriminatory power of the assay should be checked by testing organisms related to the AI virus. These would include pathogens which cause similar clinical syndromes such as Newcastle disease, infectious bursal disease, etc., and other organisms, which are likely to be found in the target sample (i.e. to demonstrate exclusivity).

1.3. Analytical sensitivity (ASe)

There are two common approaches to assessing analytical sensitivity, also known as the limit of detection. The first is to use a dilution series of the target pathogen (in this case AI virus) diluted in sample matrix and not buffer. The dilution series is usually tested using the assay under validation and a standard method. For AI, the standard method could be virus isolation or another in-house standard method of detection. This approach yields a comparative measure of the two methods (see Chapter 2.2.5). The second approach is to use a plasmid construct, containing the target sequence and test this as a dilution series in sample matrix. In this manner, the number of genome copies detectable by the test method can be estimated.

1.4. Standard test method for comparison with the candidate test method

On some occasions it is not possible to complete a full validation exercise either because samples of known analyte status are scarce (e.g. exotic diseases) or, when an emergency situation arises, the assay is required for use before it can be fully validated. Provisional recognition can be achieved provided that results through Stage 1 of the validation process compare favourably with results of a standard test method or a known established and preferably published method. Another choice for a standard method is the one used routinely in the laboratory. It is important to recognise that different methods identify different morphological or functional entities of the organism. It is therefore possible that comparison between a standard culture-based method and a new NAD technique will give rise to discrepant results (see Section B.2, Stage 2, below, for discussion on resolution of discrepancies). The choice of assessment panel is also very important and it should be as extensive as possible (see Chapter 2.2.6). If only a small panel of samples is available for evaluation, it is useful to determine if the assay passes reproducibility expectation, i.e. withstands the rigors of use in other laboratories. This requires that both laboratories use the same protocol, and same reagents, same panel of samples and similar (if not identical) equipment.

- Has the new test performed in a satisfactory manner compared to a standard method of comparison?
- Is preliminary reproducibility data acceptable
- Does the assay merit proceeding to studies on full validation (Stages 2–4)?

If lack of samples prevents continuing through the next stage of the validation pathway (Diagnostic Performance of the assay), it is acceptable to use a NAD assay that has been provisionally accepted by having been thoroughly validated through Stage 1 of validation (see the WOAH Validation Standard, Section B.2.6). Acceptance of provisional validation is fully dependent upon approval by local authorities, or through bilateral agreements between countries.

1.5. Analytical accuracy

Analytical tools, designed to provide information to characterise samples that are detected using a screening assay, only require validation of their analytical performance characteristics. So, there is no requirement to determine diagnostic sensitivity or diagnostic specificity in such cases. Examples of such approaches include PCR typing assays to determine whether a matrix-positive influenza A strain is H5 or H7, or methods to determine antibiotic resistance which are only applied to cultured bacteria. A nucleic acid based technology employed for such tests includes nano-array based methods, which introduce their own challenges due to the large amount of data generated for each sample tested. Before implementing such assays, consideration should be given to how this analysis can be accomplished. A simpler approach is to compare the results of a new analytical tool to a standard tool and permit its use as long as the results of the new and existing techniques compare favourably (Anjum *et al.,* 2007; Batchelor *et al.,* 2008).

2. Stage 2 – Diagnostic performance criteria

2.1. Diagnostic sensitivity and diagnostic specificity

Diagnostic sensitivity (DSe) and specificity (DSp) provide the principle performance indicators for use of a diagnostic assay. When determining these estimates it is vital to select sufficient numbers of samples which represent the target population for the test under assessment).It can be difficult to obtain large numbers of samples (particularly positive samples) for some exotic diseases, and negative samples for endemic diseases. In such cases, with few samples available, the amount of error allowed in estimates of DSe and DSp, of necessity, may be rather large (see the WOAH Validation Standard, Section B.2, Table 2).). If an appropriate sampling design can be employed and different independent test methods can be used to test the samples, it is possible to obtain estimates of DSe and DSp by using Bayesian methods (latent class models) (see Chapter 2.2.5). Negative reference samples are often selected from animals living in regions where the disease is not present, while positive samples are usually obtained from animals with clinical signs which have been confirmed in the laboratory. This can lead to overly optimistic estimates of DSe and DSp because the samples do not represent the whole spectrum of the disease process, ranging from non-clinical animals which may have pathogen loads that are much different from animals experiencing fulminant or chronic disease.

- **Cut-off** is the test (Ct) value selected for distinguishing between negative and positive results on a continuous scale of test values.
- **Indeterminate, intermediate, suspicious, borderline, grey zone or equivocal** are terms used synonymously for a zone of test values falling between the positive and negative cut-offs.

Samples are often categorised using current test methods such as virus isolation (VI) or bacterial culture. However, this can be problematic when validating new molecular tests, because the basis of the two test systems is different. For example, a positive bacterial culture is dependent upon the presence of a viable organism whereas nucleic acid based methods detect genomic sequences of both live and dead organisms as long as the nucleic acid is still present in the sample.VI methods can be particularly susceptible to inhibitors and contaminants present in the sample matrix, leading to an underestimate of “true positives”. This can result in apparent discrepancies where samples are positive using the new molecular test and negative by traditional methods. Various strategies for resolving such anomalies include, but are not limited to, sequencing (which can demonstrate that the pathogen of interest was present in a particular sample), or testing using another molecular approach.

To calculate DSe and DSp estimates of the candidate assay, the test results first must be reduced to categorical (positive, negative, or indeterminate) status. This is accomplished by insertion of one or two cut-off points (decision limits) on the continuous scale of test results. For example, in some circumstances it is appropriate to use a cut-off for a real time PCR assay in the region of 35 Ct, which

means that some samples that produce a higher Ct value are categorised as negative or inconclusive. For a different PCR assay, however, any sample which merely registers a Ct may be categorised as positive. The performance of a particular real-time PCR, comparative validation data, the ultimate application of the results generated, and any relevant veterinary information should be taken into account when considering the use of a cut-off.

3. Stage 3 – Reproducibility and augmented repeatability estimates

Reproducibility is a measure of the agreement between results obtained in different laboratories using the same protocol, similar (preferably the same) equipment and the same panel of samples. Ideally the panel would consist of 20–30 samples including a few which are present as quadruplicates. The panel should consist of samples that cover the dynamic range of the test with several that have activity close to, and on either side of, the test-cut-off(s). The same panel used for determination of repeatability could be used for this evaluation, but with enhanced numbers of replicates. Measurements of precision can be estimated for both the repeatability and reproducibility data (see Chapter 2.2.4 for further explanation of this topic and its application). Chapter 2.2.6 provides further information about the selection and use of reference panels.

4. Stage 4 – Programme implementation

4.1. Interpretation of test results

Best practices for programme implementation are general to all assay types (see WOAH Validation Standard). For NADs, an inherent advantage is the possibility of follow-up genomic sequencing to resolve apparent false positive results. Assays including PCRs are often validated using similar numbers of positive and negative samples. However, in surveillance programs, assay results are often applied to affirm the absence of the disease in question in locales where disease prevalence is very low and often approaching zero. In such circumstances, false positive results can be a significant problem even if the diagnostic specificity of a particular assay is high. If the DSp of an assay is 99.5% this means that one in 200 test-positive results will be false if the prevalence is close to zero. If a large number of samples are tested from a population of zero or very low prevalence, such false positive results can significantly out-number true positive results (see the WOAH Validation Standard, Section B.4.2 for further explanation of predictive values of test results as a function of disease prevalence). For NAD assays used in such circumstances, it would be good practise to confirm PCR-positive results by sequencing.

5. Monitoring of assay performance after initial validation

5.1. Monitoring the assay

Monitoring of repeatability by charting the Ct values obtained for working standard control samples provides re-assurance that the assay is performing as expected. Similarly, participation in proficiency testing schemes issued by external providers of quality assurance samples provides evidence of on-going reproducibility and also allows comparison of test accuracy if a reference standard(s) are included in each run for “normalisation” of data. Re-testing of a proportion (usually in the range of 1–5% depending on throughput) of retained samples is also employed by some laboratories to demonstrate that the assay is performing consistently between runs.

In time it may be necessary to modify the assay because the target analyte has changed, e.g. if the assay for avian influenza is to be applied in another part of the world or if new strains or lineages of a virus have emerged (see Section B.1.2, above, on the evolution of the new pandemic lineage of H1N1). RNA viruses evolve rapidly and point mutations can occur, so it is advisable to regularly confirm the nucleotide sequences of the primer and probe sites to ensure that they remain appropriate.

5.2. Minor modification of an existing validated assay

5.2.1. Technical modifications

Modifications of an assay are likely to be required, over time. For example, use of different equipment, use of a different extraction protocol or automation of particular stages will

minimally require comparison of the original validated assay with the modified version (see Chapter 2.2.8). If results of the modified version fall outside of the operating range or performance expectation of the original assay, a revalidation may be necessary.

5.2.2. Replacement of depleted reagents

It is important to assign unique identification numbers to all batches of reagents and to record the components used for particular assays. The most critical components in PCR based assays are the probes, the primers and the enzymes. Current and new batches of critical reagents should be tested in parallel prior to their introduction. However, for other reagents such as buffers and nucleotides it is usually sufficient to monitor batches to inform troubleshooting, should that become a necessity.

5.3. Major change in assay requiring revalidation

Upon occasion, application of the assay may need to be extended beyond the scope of the original intended purpose of the assay. Examples are inclusion of another host species or a population of animals from a different geographical area. In such cases it is important to revalidate the assay because of new biological considerations with their many associated variables. The precise details will depend on the extent of the change. Moving the assay into a new geographical area might mean that the analytical characteristics of the assay are still valid but that the diagnostic criteria need to be re-defined. Similarly modifications may be made to PCR primer or probe sequences to allow detection of new strains. It will then be necessary to demonstrate how the new reagents behave in terms of analytical and diagnostic accuracy compared with the previous version of the assay.

CHAPTER 2.2.4.

MEASUREMENT UNCERTAINTY

INTRODUCTION

The WOAH Validation Recommendations in Section 2.2 Validation of diagnostic tests *of this* Terrestrial Manual *provide detailed information and examples in support of the WOAH Validation Standard that is published as Chapter 1.1.6* Validation of diagnostic assays for infectious diseases of terrestrial animals. *The Term "WOAH Validation Standard" in this chapter should be taken as referring to that chapter.*

Estimation of measurement uncertainty (*MU*)*, sometimes termed measurement imprecision, is a requirement for testing laboratories based on international quality standards such as ISO/IEC 17025-2005, General requirements for the competence of testing and calibration laboratories* (*ISO/IEC 17025*)*. The measurement process for detection of an analyte in a diagnostic sample is not entirely reproducible and hence, there is no exact value that can be associated with the measured analyte. Therefore the result is most accurately expressed as an estimate together with an associated level of imprecision. This imprecision is the measurement uncertainty* (*MU*)*. MU is limited to the measurement process. It is not a question of whether the measurement is appropriate and fit for whatever use to which it may be applied. It is not an alternative to test validation, but is rightly considered a component of that process* (*see the WOAH Validation Standard, Section B.1.1*).

A. THE NECESSITY OF DETERMINING MU

To assure compliance with ISO/IEC 17025-2005 requirements, national accreditation bodies for diagnostic laboratories require MU estimates for test methods that produce quantitative results, e.g. optical densities (OD), percentage of positivity or inhibition (PP, PI), titres, cycle threshold (CT) values, etc. This includes tests, where numeric results are calculated and then are expressed as a positive or negative result at a cut-off value. For the purpose of estimating MU in serology and RT PCR, suitable statistical measures are mean target values ± 2 standard deviations (SD), which is approximately equal to a 95% confidence interval (CI), relative standard deviation (RSD = SD / mean of replicates) and coefficient of variation (CV = RSD × 100%). The concept of MU does not apply to strictly binary results (positive or negative).

1. Samples for use in determining MU

Repeatability is the level of agreement between results of replicates of a sample both within and between runs of the same test method in a given laboratory. During assay development, repeatability is estimated by evaluating variation in results of independent replicates from a minimum of three (preferably five) samples representing analyte activity within the operating range of the assay (see the WOAH Validation Standard, Sections A.2.5 and B.1.1, and Chapter 2.2.6 *Selection and use of reference samples and panels*, Section 3.1). Typically, the variation in replicate results is expressed as RSD or CV. The significant feature is that repeatability studies can be used to define the expected precision of the assay in the detection of a range of analyte concentrations.

The use of internal quality or process controls over a range of expected results has become part of daily quality control and quality assurance operations of accredited facilities (see the WOAH Validation Standard, Sections A.2.6 and B.5.1, and Chapter 2.2.6, Section 1.4). These results provide a continuous monitor relative to different aspects of repeatability, e.g. intra- and inter-assay variation, intra- and inter-operator variation and intra- and inter-batch variation, which, when subjected to statistical analysis, provide an expression of the level of robustness (precision) of a test procedure. The monitoring of assay quality control parameters for repeatability provides evidence that the assay is, or is not performing as expected. In order for control samples to provide valid inferences about assay precision, they should be treated in exactly the same way as test samples in each run of

the assay, e.g. including sample preparation such as extraction steps or dilution of serum samples for an antibody enzyme-linked immunosorbent assay (ELISA).

The variation of the results for control samples can also be used as an estimate of those combined sources of uncertainty and is called the "top-down" approach. This approach recognises that the components of precision will be manifest in the ultimate measurement. So monitoring the precision of the measurement over time will effectively show the combined effects of the imprecision associated with component steps.

The imprecision or uncertainty of the measurement process associated with a test result becomes increasingly more important the closer the test value is to the diagnostic cut-off value. This is because an interpretation is made relative to the assay threshold regarding the status of the test result as positive, negative, or inconclusive (as will be described in the following example). In this context, low positive samples, like those used in repeatability studies or as the low positive control, are most appropriate for estimation of MU. The rationale being that MU, which is a function of assay precision, is most critical at decision-making points (i.e. thresholds) which are usually near the lower limit of detection for the assay. In this chapter, the application of MU with respect to cut-off (threshold) values, whether recommended by test-kit manufacturers or determined in the diagnostic laboratory, is described.

2. Example of MU calculations in ELISA serology

For most antibody detection tests, it is important to remember that the majority of tests are measurements of antibody activity relative to a threshold against which a dichotomous interpretation of positive or negative is applied. This is important because it helps to decide where application of MU is appropriate. In serology, uncertainty is frequently most relevant at the threshold between positive and negative determinations. Results falling into this zone are also described as intermediate, inconclusive, suspicious or equivocal (see the WOAH Validation Standard, Section B.2.4).

A limited data set from a competitive ELISA for antibody to avian influenza virus is used as an example of a "top-down" approach for serology. A low positive control sample was used to calculate MU at the cut-off level.

2.1. Method of expression of MU

As the uncertainty is to be estimated at the threshold, which is not necessarily the reaction level of the low positive control serum, the relative standard deviation (RSD), or coefficient of variation (CV), if expressed as a percentage, provides a convenient transformation:

$$RSD\ (X) = SD\ (X) / (\bar{X})$$

To simplify assessment, the transformed result is regarded as the assay output result, which is the averaged across the number of replicates ($\bar{X}$). In the case of this example, a competitive ELISA, results are "normalised" (as defined in the WOAH Validation Standard, Section A.2.7) to a working standard by forming a ratio of all optical density (OD) values to the OD result of a non-reactive (negative) control (OD_N). This ratio is subtracted from 1 to set the level of antibody activity on a positive correlation scale; the greater the level, the greater the calculated value. This adjusted value is expressed as a per cent and referred to as the percentage inhibition or PI value. So for the low positive control serum (OD_L), the transformation to obtain the per cent inhibition values for the low positive control (PI_L) is:

$$PI_L = 100 \times [1 - \{OD_L / OD_N\}]$$

The relative standard deviation becomes:

$$RSD\ (PI_L) = SD\ (PI_L) / (PI_L)$$

2.2. Example

A limited data set for the AI competitive ELISA example is shown below. In the experiment, the operator tested the low positive control serum ten times in the same run. Ideally in the application of this "top down" method, a larger data set would be used, which would enable accounting for effects on precision resulting from changes in operator and assay components (other than only the control serum).

Test	*PI(%)*
1	56
2	56
3	61
4	64
5	51
6	49
7	59
8	70
9	55
10	42

Mean PI = 56.3; Std Dev (SD) = 7.9; Assays (*n*) = 10

2.3. Calculating uncertainty

From the limited data set,

RSD (PI_L) = SD/Mean 7.9/56.3 = 0.14 (or as coefficient of variation = 14%)

Expanded uncertainty (U) is the statistic defining the interval within which the value of the measure and is believed to lie within a specified level of confidence, usually 95%. Expanding the uncertainty is done by multiplying the RSD (PI_L) by a factor of 2; this allows the calculation of an approximate 95% confidence interval around the threshold value (in this case at PI = 50%), assuming normally distributed data.

U (95%CI) = 2 × RSD = 0.28

This estimate can then be applied at the threshold level

95% CI = 50 ± (50 × 0.28) = 50 ± 14%

2.4. Interpretation

Any positive result (PI > 50%) that is less than 64% is not positive with 95% confidence. Similarly, a negative result (PI < 50%) that is higher or equal to a PI of 36 is not negative at the 95% confidence level. This zone of lower confidence may correlate with the "grey zone" or "inconclusive/suspect zone" for interpretation that should be established for all tests (Greiner *et al., 1995*).

B. OTHER APPLICATIONS

The top-down approach should be broadly applicable for a range of diagnostic tests including molecular tests. For the calculation of tests using a typical two-fold dilution series for the positive control such as virus neutralisation, complement fixation and haemagglutination inhibition tests geometric mean titre (i.e. mean and SD of log base 2 titre values) of the positive control serum should be calculated. Relative standard deviations based on these log scale values may then be applied at the threshold (log) titre, and finally transformed to represent the uncertainty at the threshold. However, in all cases, the approach assumes that the variance about the positive control used to estimate the RSD is proportionally similar at the point of application of the MU, for example at the threshold. If the RSD varies significantly over the measurement scale, the positive control serum used to estimate the MU at the threshold should be selected for an activity level close to that threshold. The Australian Government, Department of Agriculture and Water Resources, has compiled worked examples for a number of diagnostic tests, which are available online at:

http://www.agriculture.gov.au/animal/health/laboratories/tests/worked-example-measurement

For real-time PCRs, replicates of positive controls with their respective cycle threshold (CT) values can be used to estimate MU using the top-down approach.

Other approaches and variations have been described, i.e. for serological tests (Dimech *et al.,* 2006; Goris *et al.,* 2009; Toussaint *et al.,* 2007). Additional work and policy documents are available from the National Pathology Accreditation Advisory Group and Life Science. The central document to MU is the Guide to the expression of uncertainty in measurement (GUM), ISO/IEC Guide (1995).

CHAPTER 2.2.5.

STATISTICAL APPROACHES TO VALIDATION

INTRODUCTION

The WOAH Validation Recommendations in Section 2.2 Validation of diagnostic tests *of this* Terrestrial Manual *provide detailed information and examples in support of the WOAH Validation Standard that is published as Chapter 1.1.6* Validation of diagnostic assays for infectious diseases of terrestrial animals. *The Term "WOAH Validation Standard" in this chapter should be taken as referring to that chapter.*

The choice of statistical methods for analysis of test validation data from laboratory experiments and from evaluation of field-based samples depends on considerations such as the experimental design and sample selection (source, number of samples, number of replicates of tests, etc.). Specific guidance about the "best approach" should be made in consultation with a statistician and should be done during the design phase before validation studies commence.

Definitions of scales of measurement:

Binary (dichotomous): Either positive or negative because that is how the test result is presented, or positive/negative at a selected threshold (cut-off) value when results are measured on an ordinal or continuous scale.

Ordinal: Measured on a scale with discrete values where higher values typically indicate more analyte, e.g. serum virus neutralisation titres.

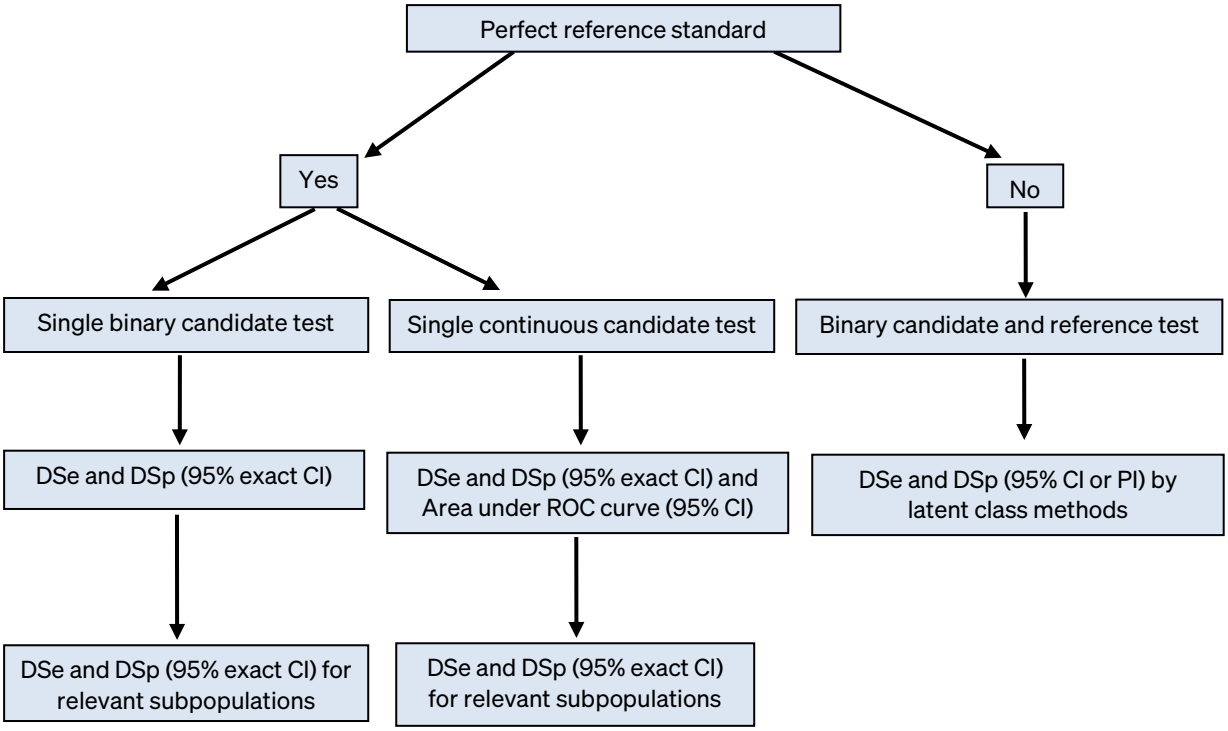
Continuous: An infinite number of measured values are theoretically possible, depending on the measurement system, e.g. optical density or per cent positive values in an enzyme-linked immunosorbent assay, and cycle threshold values from real-time polymerase chain reaction assays that are lower than the maximum number of cycles that are run in the assay.

For brevity, this annex considers commonly-used approaches for validation of a candidate test and hence, does not consider all statistical methods that might be used in practice. Methods are described to estimate the precision of an assay when repeated multiple times (repeatability and reproducibility), analytical characteristics (analytical sensitivity and specificity) and diagnostic characteristics (e.g. diagnostic sensitivity [DSe] and specificity [DSp], and area under the receiver-operating characteristic curve of an assay) used to detect an analyte in individual animals. Similar principles apply when tests are used to detect the same analyte in naturally or artificially-created sample pools from animals in aggregates (e.g. herds or flocks). In this case, the epidemiological unit is the aggregate rather than individual animals.

Statistical methods differ depending on whether a single or multiple tests are evaluated, their scales of measurement (binary, ordinal, or continuous), whether independent or dependent (paired) samples are used, and whether there is a perfectly accurate reference standard (often termed a gold standard) for comparison (Wilks, 2001). Flow charts to guide selection of statistical methods for evaluation of diagnostic accuracy measures such as sensitivity and specificity are in Figures 1 and 2.

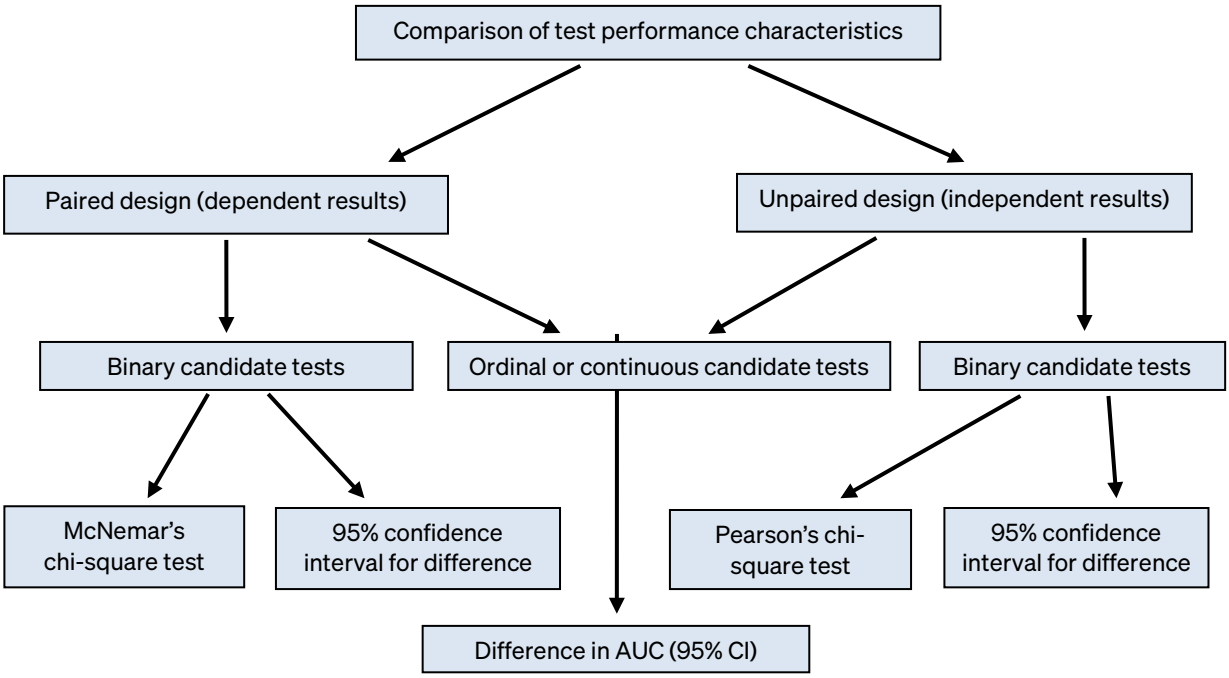
*The adequacy of the design of the study and statistical analysis may not always be reflected in the quality of reporting in scientific publications and hence, test developers and evaluators are encouraged to follow the STARD (**Sta**ndards for **R**eporting of **D**iagnostic Accuracy) checklist (Bossuyt* et al., *2003) to ensure complete reporting of all relevant information in validation studies of infectious diseases in animals.*

For guidance on analysis of measurement uncertainty data and for data for methods comparison studies refer to Chapters 2.2.4 and 2.2.8, respectively.



Abbreviations: DSe = diagnostic sensitivity; DSp = diagnostic specificity; ROC = receiver operating characteristic; CI = confidence interval; PI = probability interval.

Fig. 1. Flow chart for suggested methods of statistical analysis when a single candidate test is evaluated with and without a perfect reference standard.



Abbreviation: AUC = area under the receiver operating characteristic curve

Fig. 2. Flow chart for suggested methods of statistical analysis when sensitivities (DSe) and specificities (DSp), and the AUC of multiple tests, are evaluated with a perfect reference standard. Ordinal and continuous data should be analysed in their original form and as binary results at the recommended thresholds. Analyses should be done for both DSe and DSp where these data are available.

A. ASSAY REPEATABILITY WITHIN A SINGLE LABORATORY

An assessment of within-laboratory repeatability of an assay (often termed *precision* when the measurement is on a continuous scale) requires that a minimum of three samples having analyte concentrations within the operating range of the assay are tested in replicate by a single operator using a single test-kit lot or batch. Typically these runs will be on the same day but separate days are also possible. Use of three or four replicates of a sample rather than two is encouraged because it better captures the inherent variability in within-run assay results. Because of cost considerations, use of more than two replicates may not be feasible for all assay types (e.g. nucleic-acid detection). As described in the WOAH Validation Standard, between-run variation can be evaluated in multiple runs involving two or more operators on multiple days. The following two sections describe approaches to analysis of continuous and binary data for assay repeatability.

1. Continuous outcomes

For continuous outcomes, the simplest approach is to estimate the standard deviation (SD) of replicates of a set of samples representing the operating range of the assay. These results initially should be evaluated in a scatter plot or diagram of the mean of the replicates plotted against the SD. For assays, where the SD is proportional to the mean, the within-sample coefficient of variation (CV) is often calculated. CV is often used even when proportionality does not exist. In this case, the CV should be reported for levels of the target analyte (e.g. low, moderate and high). This is necessary because it is a common finding that CV is often larger when the concentration of target analyte is low. In general, an estimate of uncertainty in the CV values (e.g. 95% confidence interval [CI]) should also be calculated. Where the CV values are fairly constant over the range of test values, this can be done using the results of all samples. Where CV differs according to analyte concentration, separate 95% CI should be calculated for each analyte category based on the number of samples tested at each level. Methods for CI calculation for CV and the difference in two CV for normal data are described in Donner & Zou (2012).

$$CV = \frac{\text{SD of replicates}}{\text{Mean of replicates}}$$

where: CV = Coefficient of variation
SD = Standard deviation

If the experimental design includes evaluation of multiple factors such as different operators and run days, other approaches such as variance component models (mixed models) may be needed should the goal be to decompose the variation into the sum of several components that can be readily interpreted. Variance components models can also be used for reproducibility data (see Section B).

2. Binary outcomes

In general, quantitative results should be used for evaluation of assay precision when data are available in that form, even though results might be dichtomotised for reporting purposes. For inherently binary tests which yield positive or negative results, the kappa statistic can be used to quantify the agreement of test results beyond chance. Kappa ranges from 0 (no agreement beyond chance) to 1 (perfect agreement beyond chance) but there is much conjecture about how kappa values should be interpreted (Fleiss *et al*., 2003; Landis & Koch 1977). Better agreement is typically expected when test results are well away from the cut-off points and hence, some samples with intermediate/suspicious values should be tested to avoid overly optimistic assessments of agreement. A weighted version of kappa for ordinal results (e.g. negative, suspicious, and positive) can be used to recognise that a large discrepancy (e.g. two category difference) is more serious than a smaller discrepancy (e.g. one category difference). Ninety-five per cent CI should be reported for unweighted or weighted estimates of kappa (Fleiss *et al.,* 2003).

Table 1. Examples of Kappa calculations for binary outcomes

Example 1: Kappa calculation based on repeated test results classified as positive or negative

Test result	***Positive***	***Negative***
Positive	90	5
Negative	10	95
	100	100

Kappa = 0.85 (95% CI = 0.78 to 0.92)

Example 2: Kappa calculation based on repeated test results classified into three categories (positive, suspicious, or negative)

Test result	*Positive*	*Suspicious*	*Negative*
Positive	80	10	10
Suspicious	15	75	10
Negative	5	15	80
	100	100	100

Kappa = 0.68 (95% CI = 0.61 to 0.75). Weighted kappa = 0.70. (95% CI = 0.61 to 0.79)

B. ASSAY REPRODUCIBILITY AMONG LABORATORIES

Assay precision will vary according to routine implementation, e.g. different operators, different test sites, using different kit lots, or on different days. Most commonly, the term *reproducibility* is applied to assessment of precision of the selected assay in multiple laboratories. Factors held constant should be described to allow interpretation of results in context to the actual testing situation. Reproducibility studies can be done independently of or in association with repeatability studies but should be done in a blinded fashion. As suggested in the WOAH Validation Standard, at least three laboratories should test a minimum of 20 samples with identical aliquots going to each laboratory.

Intraclass correlation coefficient represents the similarity or correlation of any two measurements made on the same sample. The ICC takes values between 0 and 1 with values closes to 1 indicating minimal measurement error. Conversely, values close to 0 indicate a large amount of measurement error.

Statistical methods for analysis of studies of assay reproducibility among laboratories are similar to those used for assessment of within-laboratory repeatability. However, as part of an among laboratory study, it might be considered important to assess and rank variability in test results from multiple sources (often termed a class). For example, if a study was designed to test an assay in three laboratories each using two highly-trained technicians and running the samples in duplicate on two kit lots, each test sample would be tested 24 times. The selected factors (laboratory, technician, kit lot, replicate result) can be considered to be fixed or random depending on how they are selected and whether they are representative of the target population. For this study design, variance components can be estimated for each class (example is Dargatz *et al.,* 2004) and the intraclass (intracluster) correlation coefficient (ICC) can be estimated as a measure of the similarity of sample results (Bartlett & Frost, 2008).

1. When a technical modification of the test method is made

After an assay has been validated for use in a controlled laboratory environment, it may be considered for use in a very different environment (such as a pen-side application). Because of the more extreme changes, for example severe temperature fluctuations which often occur at pen-side, it would be expected that the two tests might behave very differently in their different environments. In fact, rather than random measurement error which applies to the assessment of within or among laboratory measurement error, it is anticipated that the values in such a study likely would be interpreted as a systematic measurement error, which would be the case if the values provide an over- or under-estimate of the true value. For the example of a test run on split samples pen-side and in a laboratory, the mean of the differences between the pen-side value and the within laboratory value (true value) for the same sample should be reported with a 95% CI. If the 95% CI excludes zero, there is evidence of systematic deviation of test results when used pen-side compared within the laboratory. When such a systematic deviation in test results occurs, the pen-side test results are not comparable with those from the laboratory-based validated assay. To validate the pen-side assay, either it is subjected to a “technical modification” that is then evaluated in a methods comparison study (see Chapter 2.2.8) or a full re-validation of the pen-side application is required.

Similar approaches can be used to assess method changes within a laboratory to determine whether there is systematic or random variation in the results.

Example: The following unpublished data were obtained comparing two extraction methods (old and new on split samples) on cycle threshold (CT) values for a real-time polymerase chain reaction (PCR) for bluetongue. The data (n=10) represent means of sample duplicates.

Old method: 25.6, 24.5, 21.3, 26.8, 25.2, 30.2, 31.2, 32.8, 31.8, 34.9

New method: 23.1, 21.0, 18.2, 25.2, 24.7, 28.6, 30.4, 32.2, 31.3, 34.7

The mean difference between the two methods (old minus new) was –1.49 (95% CI = –2.33 to –0.64) with a two-tailed probability of p=0.003. Because the 95% CI excludes zero, this indicates a systematically lower CT value when the new extraction method is used. A Bland–Altman plot (Bland & Altman, 1999; Fig. 3) can be used to graphically depict how the difference changes as a function of the mean value of the old and new method. For these data, the difference appears to decrease for higher CT values but the sample size is small.

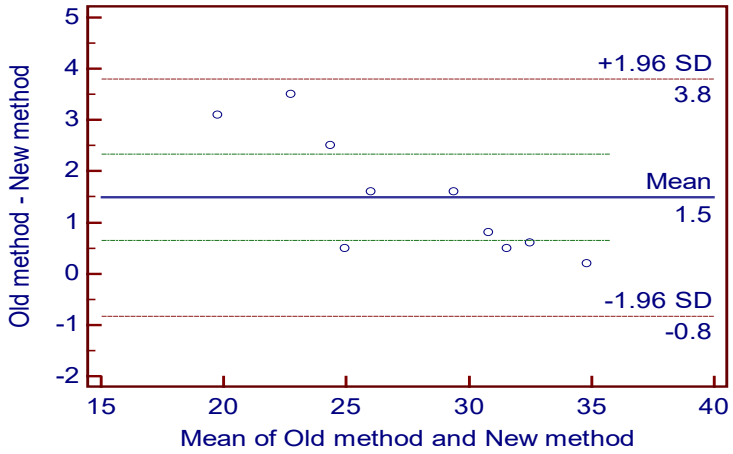


Fig. 3. Bland-Altman plot of mean difference (y axis) in CT values as a function of the mean value of the old method and new method (n=10).

C. ANALYTICAL SENSITIVITY (ASE, SYNONYM = LIMIT OF DETECTION: LOD)

Analytical sensitivity can be estimated using a dilution-to-extinction (DTE) experiment in which serial dilutions of a known quantified amount of target analyte are made into the appropriate sample matrix. This known quantified amount might be from an in-house or national/international reference standard or a field sample whose analyte concentration has been determined. Parallel runs of a comparison standard can be done but are not essential, unless the study is one in which a minor change in a validated assay is being compared with the original validated assay. The DTE approach can be used if the analyte is measured qualitatively or quantitatively. In the latter case, the test result is reclassified as positive or negative.

The approach to analysis of LOD data depends on the experimental design. For example, suppose that a study was done in which 10^8 colony-forming units (CFU) of a bacterium were spiked into 10 g faeces to achieve a concentration of 10^7 CFU/g. This sample was then diluted in tenfold serial dilutions to 10^1 CFU/g. The experiment was repeated three times. If all replicates at 10^3 CFU/g were detected but none at 10^2 CFU/g, the LOD could be conservatively estimated as 10^3 CFU/g. If a precise estimate of the LOD were needed, a second stage experiment could be designed to determine the LOD with a greater certainty using a series of finer dilutions, e.g. twofold, encompassing the interval between 100% detection and 0% detection identified in the first experiment. The LOD endpoint often is chosen to be 95%; in an experiment with 20 replicates, this corresponds to the dilution where 19 replicates for analyte were positive. The important point is that the chosen probability point for the LOD (whether 95%. 50% of another value) should be specified and used consistently if results of multiple tests are being compared. The LOD can be estimated using the Spearman-Kärber non-parametric approach, or by logistic regression or probit analysis. The greater the number of replicates for each dilution, the more precise the estimate of LOD.

Example: Guthrie *et al.* (2013) made a twofold dilution series of an AHSV-positive horse blood (10^{-3} dilution), which covered the non-linear range of the assay. The extraction was repeated 25 times and samples were tested by

AHSV real-time PCR. The real-time PCR results for the 15 dilution points were used in a probit analysis to calculate the 95% LOD (i.e. input concentration giving a positive real-time real-time PCR result in 95% of the replicates (Burns & Valdivia, 2008). The 95% LOD was estimated to be at a dilution of 3.02×10^{-6}, as shown in Figure 4, and corresponded to a quantification cycle of 35.71 in the real-time PCR. CI for the estimate were not reported.

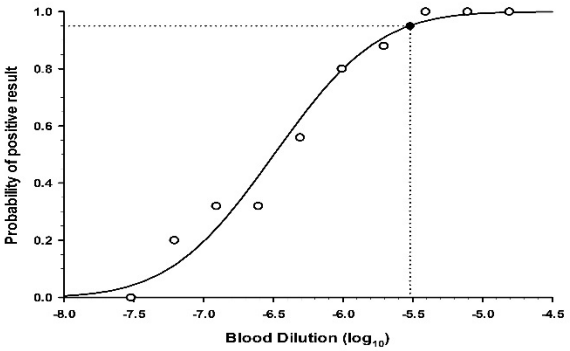

Fig. 4. Estimated 95% limit of detection of AHSV in horse blood (*log_{10}*), which is shown by the dashed line.

D. ANALYTICAL SPECIFICITY (ASP)

Analytical specificity can be described in at least three distinctive ways: selectivity, exclusivity (synonym: cross-reaction profile), and inclusivity (as described in the WOAH Validation Standard). The latter two measures should be reported on a per lineage, isolate, species or genus basis, as appropriate for the target analyte and the intended purpose of the test. For screening tests, a broader and more inclusive specificity is required than for a confirmatory test that may distinguish between isolates that, for instance, vary in pathogenicity. Because the choice of related organisms is subjective and often dependent on the types and numbers of samples, the exclusivity result should be reported qualitatively, e.g. the percentage of related agents that cross-reacted in the assay with a listing of potential cross-reacting agents that were evaluated. Similarly, inclusivity is reported as a percentage of the serovars, strains, genera and species detected by the assay, as appropriate for the target analyte.

E. DIAGNOSTIC PERFORMANCE OF THE ASSAY

Diagnostic performance of an assay is mostly commonly measured as sensitivity (DSe) or specificity (DSp) or a combined measure of DSe and DSp such as the likelihood ratio of a positive of negative result. Likelihood ratios for intervals of test results can also be calculated when it is important to retain information on the magnitude of the test result rather than use it in a dichotomised form. For more information on use and calculation of likelihood ratios, see Gardner & Greiner (2006) and Gardner *et al.* (2010). The latter paper includes an example for porcine toxoplasmosis with CI calculations by two methods.

Statistical uncertainty about diagnostic performance parameters, e.g. DSe and DSp, should be presented as confidence intervals (CI). Typically, a 95% CI is used and its width (precision of the estimated value) depends strongly on the sample size used for parameter estimation. Exact CI are preferred to normal approximations because they avoid upper limits that exceed 100%.

DSe and DSp can be estimated when the reference or comparison method is perfectly sensitive and specific or when the reference standard is imperfect. In general, most ante-mortem reference standards in common use in diagnostic laboratories are imperfect and hence, necropsy with testing of multiple tissues by ancillary tests such as culture and/or histopathology often is necessary if the results of the reference standard are to be considered to be the truth. For most test validation studies for animal diseases, this latter option is not feasible or cost-effective except for a limited number of samples.

1. DSe and DSp with a perfect reference standard

The candidate test may yield results on binary (dichotomous), ordinal (e.g. titre) or continuous scales. For the latter two scales, results need to be dichotomised before DSe and DSp can be calculated, i.e. a cut-off (threshold) needs to be established. Exact binomial 95% CI are recommended for DSe and DSp (Greiner & Gardner, 2000) because the normal approximation may not yield appropriate CI when parameter estimates are close to 1.

Example: indirect enzyme-linked immunosorbent assay (I-ELISA)

		Number of animals	
		Known antibody positive (369)	Known antibody negative (198)
Test results	Positive	287 TP	FP 1
	Negative	FN 82	TN 197
		Diagnostic sensitivity* TP/(TP + FN) **77.8%** (73.2 – 81.9%)*	Diagnostic specificity* TN/(TN + FP) **99.5%** (97.2 – 99.9%)*

TP and FP = true positive and false positive, respectively

TN and FN = true negative and false negative, respectively

*95% exact binomial confidence limits for DSe and DSp

When the reference standard is not applied to all positive and negative test results (partial verification), corrected estimates of DSe and DSp should be made as described in Greiner & Gardner (2000) to account for different sampling probabilities in the test-positive and test-negative groups.

For assays yielding ordinal (e.g. titre values) or continuous results (e.g. ratios of test sample to positive control sample values in an ELISA), estimates of DSe and DSp should be complemented with estimates of the area under the receiver-operating characteristic (ROC) curve. ROC analysis provides a cut-off-independent approach for evaluation of the global accuracy of a test where results are measured as ordinal or continuous values. The area under the ROC curve provides a single numerical estimate of overall accuracy ranging from 0.5 (useless test) to 1 (perfect test). The main justification for ROC analysis is that cut-off values for test interpretation may change depending on the purpose of testing (e.g. screening versus confirmation) and with the prevalence of infection, the costs of test errors, and the availability of other tests. Detailed descriptions of ROC analysis are presented elsewhere (Gardner & Greiner, 2006; Greiner *et al.,* 2000; Zweig & Campbell, 1993). When multiple ordinal or continuous tests are compared, the difference in the area under the curve with a 95% CI should be calculated. Methods for calculating differences vary for independent and dependent samples and are implemented in many statistical programs (Gardner & Greiner, 2006). Examples of a dot diagram for results of a single ELISA and ROC curves for two ELISAs are shown in Figures 5 and 6.

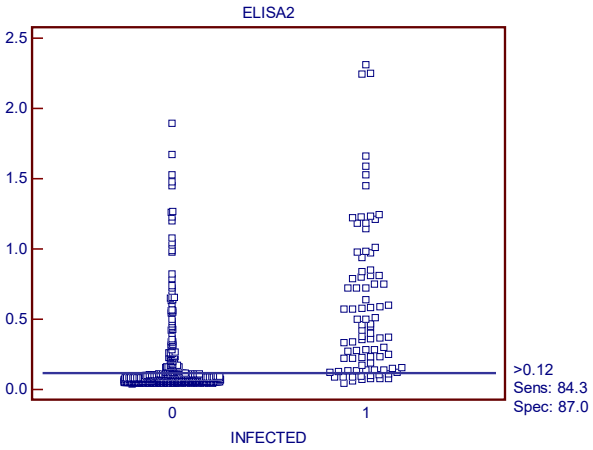

Fig. 5. Dot diagram of ELISA results for non-infected (Code = 0) and infected (Code = 1) animals.

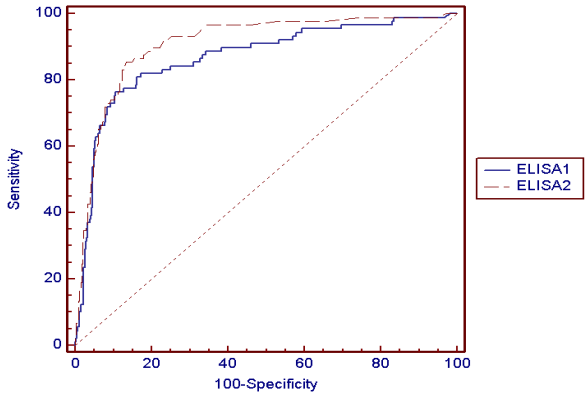

Fig. 6. Receiver-operator characteristic curve for two ELISAs.

In the absence of a perfect reference standard, it is also possible to estimate the AUC using latent class (LC) models. For example, LC models can be applied to normally distributed data from two dependent tests (see for example Choi *et al.,* 2003) and using semiparametric approaches (Branscum *et al.,* 2008). LC models for continuous data including censored or truncated data that occur with real-time PCR assays are not described in this validation guideline because of their complexity. However, LC models for binary test results and an example application are described in Section E.3.

2. Comparison of DSe and DSp estimates for two tests with a perfect reference standard

Often, investigators might wish to compare DSe values in subpopulations of infected animals, e.g. clinically versus subclinically infected, or DSp values in different geographical areas. Since these are independent samples, the comparisons can be made statistically by Pearson's chi-square test for homogeneity. Alternately, separate 95% CI and a 95% CI for a difference in two proportions can be calculated. When the DSe (or DSp) of two tests are compared on the same set of infected (or non-infected) samples in a paired design, the test results are no longer independent. Statistical methods such as McNemar's chi-square can be used to test the hypothesis of equal sensitivities (specificities) when testing is done on the same samples.

Example: Five antibody detection tests were evaluated for diagnosis of bovine paratuberculosis in dairy cows in known infected and non-infected herds, as determined by faecal culture results and herd history. The following data tables were generated based on the original data before subsequent publication in Collins *et al*. (2005). In the publication, one herd was removed from the analysis. The example is used for demonstration purposes to show the tabular layout for calculation of DSe and DSp and statistical evaluation.

Infected

	T_{2+}	T_{2-}	
T_{1+}	124	74	198
T_{1-}	8	243	251
	132	317	449

Non-infected

	T_{2+}	T_{2-}	
T_{1+}	3	27	30
T_{1-}	16	366	382
	19	393	412

Sensitivity of T1 = 198/449 = 44.1%

Sensitivity of T2 =132/449 = 29.4%

Specificity of T1 = 382/412 = 92.7%

Specificity of T2 = 393/412 = 95.4%

Sensitivities differed significantly ($p<0.0001$), but specificities did not ($p= 0.126$) based on a two-tailed McNemar's chi-square test. Sensitivity and specificity covariances (see Gardner *et al*., 2000 for details) can also be calculated to indicate whether the tests are conditionally independent or dependent, given infection status. For these data, the sensitivity covariance (calculated using the infected table on the left) was 0.147 ($p < 0.0001$ by Pearson's chi-square) indicating strong dependence of the two tests when used in infected animals. The specificity covariance (calculated using the non-infected table on the right) was 0.004 ($p = 0.152$ by Pearson's chi-square) indicating no significant dependence.

An additional example based on porcine toxoplasmosis data is presented in Gardner *et al*. (2010).

3. DSe and DSp without a perfect reference standard

Advances in statistical methodology, specifically the development of latent class (sometimes termed "no-gold-standard") models, now allow investigators to liberate themselves from the restrictive assumption of a perfect reference test and estimate the accuracy of the candidate test(s) and the reference standard with the same data (Enoe *et al.,* 2000; Hui & Walter, 1980).

Latent class (LC) models, either using maximum likelihood or Bayesian methods, can be used for estimation of DSe and DSp when joint test results are available from multiple tests applied to animals in multiple populations (e.g. herds or geographical areas). Not all LC models for estimation of DSe and DSp will be statistically identifiable for inference. A model is identifiable if it is theoretically possible to determine the true value of model parameters after obtaining an infinite number of observations from it. In essence, this equates to having a unique set of values for the parameters of interest (DSe, DSp). Bayesian approaches are especially suited to situations where prior information is available about DSe and/or DSp and when the estimation problem is not identifiable (Branscum *et al*., 2005).

The simplest one-population LC model that is identifiable is when three conditionally independent are run on the same samples. The constraint of independence of three tests may be difficult to achieve in practice unless the target analyte differs among tests. Hence, a commonly used approach in animal health is to run two tests on all samples from animals in two populations because it is less costly and assumptions of conditional independence may be more reasonable. The two-test two-population model also requires the assumptions of constant sensitivity and specificity across the two populations, and distinct prevalences. The assumption about constant sensitivity may be difficult to verify and is unlikely to be correct if one population has clinically affected animals and the other population has subclinically affected animals because many published studies have shown that test sensitivity is greater in clinically affected animals. If one of the two populations is known to be pathogen-free (prevalence is zero) while the other population is known to have a non-zero prevalence, the former population can be used for estimation of DSp and this will facilitate estimation of DSe in the infected population.

WOAH-listed diseases where DSe and DSp have been estimated with Bayesian methods include ovine brucellosis (Praud *et al*., 2012), Q fever (Paul *et al*., 2013), trypanosomosis (Bronsvoort *et al*., 2010), bovine tuberculosis (Clegg *et al*., 2011), foot and mouth disease (Bronsvoort *et al*., 2006), African horse sickness (Guthrie *et al*., 2013) and infectious salmon anaemia virus (Caraguel *et al*., 2012).

The WinBUGS software[1] allows easy implementation of Markov-chain Monte Carlo methods for Bayesian estimation (Lunn *et al.,* 2000) and simple maximum likelihood analyses can be done using a web-based interface (Poulliot *et al.,* 2002). Prior information about model parameters used in the Bayesian analyses may affect the final estimates depending on the relative strength of evidence provided by the priors (level of prior uncertainty) and the data (uncertainty attributable to finite sample sizes). Therefore, the sources of prior information must be well documented in Bayesian analyses and it may be desirable to repeat the analysis using non-informative priors on all parameters when the model is identifiable.

Maximum likelihood – a method for estimation of the most likely values for the parameters of interest based on the value of likelihood function for the data.

Bayesian methods – incorporate relevant prior information or knowledge about one or more tests in addition to the likelihood function for the data. With large sample size, maximum likelihood and Bayesian methods will yield similar inferences.

It is important to note that LC analysis cannot correct for biases inherent in poorly designed studies. The methods should be used carefully and include a thorough evaluation of underlying assumptions (e.g. conditional dependence, constant sensitivity and specificity across populations, and distinct prevalences), the effects of use of the selected prior distributions on posterior inferences as described in the previous paragraph, and convergence of Markov chains in a Bayesian analysis (Toft *et al.,* 2005).

Example: Guthrie *et al*. (2013) estimated the DSe and DSp of a quantitative real-time PCR and conventional virus isolation (VI) for detection of African horse sickness (AHS) virus in whole blood samples using a two-test two-population Bayesian latent class model. Two populations of South African thoroughbred horses (503 AHS suspect cases and 503 healthy horses from the AHS virus controlled zone) were tested by PCR and VI. For the 503 suspect cases the joint test results were: PCR+VI+ (*n*=156). PCR+VI– (*n*=184), PCR–VI+ (*n*=0), and PCR–VI– (*n*=163). All 503 healthy horses were PCR–VI–. Various models (conditional independence and conditional dependence) were fitted to the data and a second population of healthy horses was also included in some analyses.

Models were run in WinBUGS 1.4.3 (Lunn *et al.,* 2000) with the first 5000 iterations discarded and the next 50,000 iterations used for posterior inferences (medians and 95% probability intervals for DSe and DSp. Model convergence was assessed by visual inspection of trace plots of iterated values and running multiple chains from dispersed initial values. The conditional independence model fitted with non-informative beta (1,1) priors on DSe and DSp of both tests yielded almost identical results to the model which used a highly informative beta (9999,1) prior for the DSp of VI. Estimated medians values and 95% probability intervals (sometimes termed credible intervals) in parentheses from the conditional independence model with non-informative priors were:

PCR sensitivity = 0.996 (0.977–0.999)

PCR specificity = 0.999 (0.993–1.0)

VI sensitivity = 0.458 (0.404–0.51)

VI specificity = 0.999 (0.998–1.0)

The results indicated a twofold higher DSe of PCR compared with VI and comparable DSp of both tests. For a complete description of the modelling approach see Guthrie *et al.* (2013).

4. Comparison of DSe and DSp estimates for two tests without a perfect reference standard

If a Bayesian approach is used in WinBUGS to analyse the joint test data from multiple populations, the difference in sensitivities (specificities) can be readily estimated and the probability that the sensitivity (specificity) of one test exceeds the other can be estimated with the STEP function.

Example: For the results of the Guthrie *et al.* (2013) data in Section E.3, the 95% probability intervals (PI) for DSe did not overlap but there was marked overlap in the 95% PI for DSp. The corresponding probability values obtained from the STEP function were 1 and 0.24, respectively. These values indicate certainty that the DSe differ but the probability that the DSp differ is small (less than 0.5).

CHAPTER 2.2.6.

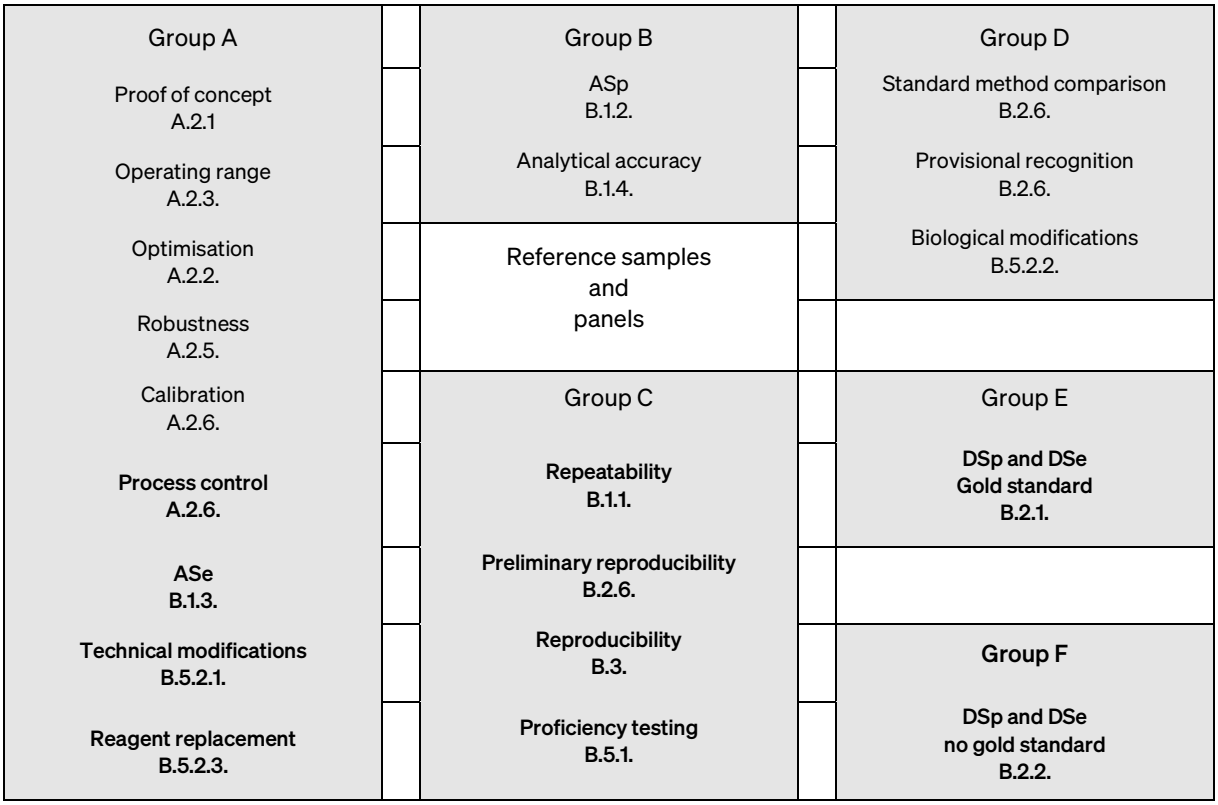
SELECTION AND USE OF REFERENCE SAMPLES AND PANELS

INTRODUCTION

The WOAH Validation Recommendations in Section 2.2 Validation of diagnostic tests *of this* Terrestrial Manual *provide detailed information and examples in support of the WOAH Validation Standard that is published as Chapter 1.1.6* Validation of diagnostic assays for infectious diseases of terrestrial animals. *The Term "WOAH Validation Standard" in this chapter should be taken as referring to that chapter.*

Reference samples and panels are essential from the initial proof of concept in the development laboratory through to the maintenance and monitoring assay performance in the diagnostic laboratory and all of the stages in between. The critical importance of reference samples and panels cannot be over-emphasised. The wrong choice of reference materials can lead to bias and flawed conclusions right from development through to validation and use. Therefore, care must be exercised in selecting reference samples and designing panels.

Fig. 1. Reference samples & panels grouped based on similar characteristics and composition. The topics and alphanumeric subheadings (e.g. Proof of Concept, A.2.1) refer to the relevant section in the WOAH Validation Standard.



ASp = Analytical specificity; ASe = Analytical sensitivity; DSp = diagnostic specificity; DSe = diagnostic sensitivity

As can be seen in Figure 1, reference samples and/or panels are mentioned throughout the WOAH Validation Standard. Reference materials are substances whose properties are sufficiently homogenous and well established to be used for the calibration of an apparatus, the assessment of a measurement method, or for assigning values to materials[1]. In the context of test method validation, reference materials or samples contain the analyte of interest in varying concentrations or activities and are used in developing and evaluating the candidate assay's analytical and diagnostic performance characteristics. In our case, analyte means the specific component of a test sample that is detected or measured by the test method, e.g. antibody, antigen or nucleic acid. These reference samples may be sera, fluids, tissues, excreta, feed and environmental samples that contain the analyte of interest and are usually harvested from infected animals and their environments. However, in some cases, they may be prepared in the laboratory from an original starting material (e.g. a dilution of a high positive serum in negative serum) or perhaps created by spiking the chosen matrix with a derived analyte (e.g. a bacterial or viral culture, a recombinant/expressed protein, or a genomic construct). Whether natural or prepared, they are used in experiments throughout the development process, carry over into the validation pathway and can be used to monitor performance throughout the lifespan of the assay.

In Figure 1, reference samples and panels are grouped based on similar characteristics and composition and these groupings will be the basis for the following descriptions. As a cross-reference, the appropriate Section of the WOAH Validation Standard is indicated under each particular application of the reference sample or panel.

Reference samples may be used for multiple purposes from the initial stages of development and optimisation, through Stage 1 and into continual monitoring and maintenance of the assay. Wherever possible, large quantities of these reference samples should be collected or prepared and preserved for long-term use. Switching reference samples during the validation process introduces an intractable variable that can severely undermine interpretation of experimental data and therefore, the integrity of the development and validation process. For assays that may target multiple species, the samples should be representative of the primary species of interest. It is critical that these samples reflect both the target analyte and the matrix in which it is found in the population for which the assay is intended. The reference materials should appropriately represent the range of analyte concentration to be detected by the assay.

It is important to emphasise that, no matter whether reference samples are selected from natural sources or prepared in the laboratory, all selection criteria or preparation procedures, as well as testing requirements, need to be fully described and put into document control. Not only is this good quality management practice, but it will provide both an enhanced level of continuity and confidence throughout the lifespan of the assay.

A. GROUP A

The question of pooling of samples to create a reference sample is often asked. If reference material is harvested from a single animal, it is important to ascertain whether or not it is representative of a typical course and stage of infection within the context of the population to be tested. If not, this could lead to bias and flawed conclusions related to validation. Pooling is a good alternative but it is imperative to pool from animals that are in a similar phase of infection. This is particularly important for antibody detection systems. Pooling also addresses the issue of the larger quantities of reference material to be stored for long term use, especially when dealing with smaller host species. Before pooling any samples, it is preferable that they be independently tested to demonstrate that they are similar with respect to analyte concentration and/or reactivity. There should be an assessment following pooling to ensure that unforeseen interference is not introduced by the pooling of multiple samples, for example differing blood types or antibody composition within the independent samples could cross-react within the pool, thus causing the pooled sample to behave differently in the specified assay than the individual samples when tested independently.

It is often difficult to obtain individual samples that truly represent analyte concentrations or reactivities across the spectrum of the expected range. Given the dynamics of many infections or responses to pathogens,

1 https://www.techlab.fr/Commun/UK_Def_MRC.asp

intermediate ranges are often very transient. In the case of antibody responses, early infection phases in individual animals often result in highly variable and heterogeneous populations of antibody isotypes and avidities. In general, these do not make good reference samples for assessing the analytical characteristics of an assay. They are nonetheless important for different types of reference panels as will be discussed later. For most applications in Group A, it is acceptable to use prepared samples that are spiked with known concentrations of analyte or a dilution series of a high positive in negative matrix to create a range of concentrations.

Whether natural or prepared, reference samples should represent the anticipated range of analyte concentrations, from low to high positive, which would be expected during a typical course of infection. A negative reference sample should be included as a background monitor. If a negative (matrix) is used as diluent for preparation of a positive reference sample (e.g. a negative serum used to dilute a high positive serum or tissue spiked with a construct), that negative should definitely be included as the negative reference sample.

As mentioned above, all reference samples should be well characterised. This includes documentation on both the pathogen and donor host. For pathogens, this may include details related to strain, serotype, genotype, lineage, etc. The source of the host material should be well described with respect to species, breed, age, sex, reproductive status, vaccination history, herd history, etc. Wherever possible, the phase of infection should be noted. This could include details related to clinical signs, antibody profiles, pathogen load or shedding, etc. Equally important, tests that are used to determine disease/infection status need to be well documented (see Section E of this chapter for further explanation). In some cases, experimental infection/exposure may be the only viable option for the production of reference material. In this case, all of the above considerations plus the experimental protocol should be detailed.

Above all else, natural or prepared, reference materials must be unequivocal with respect to their status as representing either a true positive or a true negative sample. This may require that the status be confirmed using another test or battery of tests. For example, many antibody reference sera are characterised using multiple serological tests. This provides not only confidence but additional documented characteristics that may be required when attempting to replace or duplicate this reference material in the future.

Recommendations regarding stability and storage of reference materials are available: https://www.woah.org/en/what-we-offer/veterinary-products/#ui-id-4

1. Proof of concept (WOAH Validation Standard, Section A.2.1)

The WOAH Validation Standard states that test methods and related procedures must be appropriate for specific diagnostic applications in order for the test results to be of relevance. In other words, the assay must be 'fit for purpose'. Many assays are developed with good intentions but without a specific application in mind. At the very outset, it is critical that the diagnostic purpose(s) should be defined with respect to the population(s) to be tested. The most common purposes are listed in broad terms in Section A of the WOAH Validation Standard. As such, they are inclusive of more narrow and specific applications. However, these specific purpose(s) need to be clearly defined from the outset and are critically important in the context of a fully validated assay. As will be seen in the following descriptions, clearly defining the application will have impact on both the selection of reference samples and panels and the design of analytical and diagnostic evaluations.

2. Operating range (WOAH Validation Standard, Section A.2.3) and analytical sensitivity (WOAH Validation Standard, Section B.1.3)

2.1. Analytical approaches

The operating range of the assay is the interval of analyte concentrations (amounts) over which the method provides suitable accuracy and precision. It also defines the lower and upper detection limits the assay. To establish this range, a high positive reference sample is selected. This high positive sample, natural or prepared, is serially diluted to extinction in a negative matrix representative of sample matrix of samples from animals in the population targeted by the assay. This includes antibody assays where a high positive reference serum should be diluted in a negative reference serum to create the dilution series. Analytical sensitivity (ASe) is measured by the lower limit of detection (LOD) of an analyte in an assay. The same high positive reference sample may be used to determine both the operating range and the analytical LOD.

2.2. Comparative approaches

If the intended purpose is to detect low levels of analyte or subclinical infections, it may be difficult to obtain the appropriate reference materials from early stages of the infection process. In some cases, it may be useful to determine a comparative ASe by running a panel of samples on the candidate assay and on another independent assay. Ideally this panel of samples would be serially collected from either naturally or experimentally infected animals and should represent infected animals early after infection, on through to the development of clinical or fulminating disease if possible. This would provide a relative comparison of ASe between the assays, as well as, a temporal comparison of the earliest point of detection relative to the pathogenesis of the disease.

An experiment like the one described above, provides a unique opportunity to collect reference samples representing a natural range of concentrations that would be useful for other validation purposes. Care must be taken to avoid use of such samples when inappropriate (consult Group D below). Wherever possible serial samples should be collected from at least five animals throughout the course of infection. In cases where sampling is lethal (e.g. requiring the harvest of internal organ tissues), the number of animals required would be a minimum of five per sampling event. For smaller host species, this number may need to be increased in order to collect sufficient reference material. Given that experiments like this require a high commitment of resources, it would be wise to maximise the collection of not only the currently targeted reference samples but additional materials (e.g. multiple tissues, fluids, etc.) that may be useful as reference materials in the future.

3. Optimisation (WOAH Validation Standard, Section A.2.2) and preliminary repeatability (WOAH Validation Standard, Section A.2.8)

Optimisation is the process by which the most important physical, chemical and biological parameters of an assay are evaluated and adjusted to ensure that the performance characteristics of the assay are best suited to the intended application. At least three reference samples representing negative, low and high positive may be chosen from either natural or prepared reference samples. Optimisation experiments are rather exhaustive especially when assays with multiple preparatory and testing steps are involved. It is very important that a sufficient quantity of each reference sample be available to complete all optimisation experiments. Changing reference samples during the course of optimisation is not recommended as this will result in the addition of an uncontrolled variable and a disruption in the continuity of optimisation evidence.

Assessment of repeatability should begin during assay development and optimisation stages. Repeatability is further verified during Stage 1 of assay validation (Section B.1.1). The same reference samples should be used for both processes, again to provide continuity of evidence.

4. Calibration and process controls (WOAH Validation Standard, Section A.2.6)

4.1. International, national or in-house analyte reference standards

International reference standards are highly characterised, contain defined concentrations of analyte, and are usually prepared and held by international reference laboratories. They are the reagents to which all assays and/or other reference materials should be standardised. National reference standards are calibrated by comparison with an international standard reagent whenever possible. In the absence of an international standard, a national reference standard may be selected or prepared and it then becomes the standard of comparison for the candidate assay. In the absence of both of the above, an in-house standard should be selected or prepared by the development laboratory within the responsible organisation. All of the standard reagents, whether natural or prepared, must be highly characterised through extensive analysis, and preferably the methods for their characterisation, preparation, and storage have been published in peer-reviewed publications. These reference standards should also be both stable and innocuous.

Reference standards, especially antibody, are usually provided in one of two formats. They may be provided as a single positive reagent of given titre with the expectation that the candidate assay will be standardised to give an equivalent titre. This is a straight forward analytical approach but many of these ‘single’ standards have been prepared from highly positive samples as a pre-dilution in a negative matrix in order to maximise the number of aliquots available. The drawback here is that there is no accounting for any potential matrix effect in the candidate assay as there is no matrix control

provided. The other approach is to provide a negative and a low and high positive set of reference standards that are of known concentrations or reactivities and are within the operating range of the standard method that was used to prepare them. This compensates for any potentially hidden matrix effect. In addition, this set of three acts as a template for the selection and/or preparation of process controls (discussed below).

Classically, the above standards usually have been polyclonal antibody standards and to a lesser extent, conventional antigen standards used for calibration of serological assays. However, today, reference standards could also be monoclonal antibodies or recombinant/expressed proteins or genomic constructs, if they are to be used to calibrate assays to a single performance standard.

4.2. Working standards or process controls

Working standard reagent(s), commonly known as quality or process controls, are calibrated to international, national, or in-house standard reagents. They are selected or prepared in the local matrix which is found in the population for which the assay is intended. Ideally, negative and both low and high positive working standards should be selected or prepared. Concentrations and/or reactivities should be within the normal operating range of the assay. Large quantities should be prepared, aliquoted and stored for routine use in each diagnostic run of the assay. The intent is that these controls should mimic, as closely as possible, field samples and should be handled and tested like routine samples. They are used to establish upper and lower control limits of assay performance and to monitor random and/or systematic variability using various control charting methods. Their daily performance will determine whether or not an assay is in control and if individual runs may be accepted. As such, these working reference samples are critically important from a quality management standpoint.

5. Technical modifications (WOAH Validation Standard, Section B.5.2.1)

Technical modifications to a validated assay such as changes in instrumentation, extraction protocols, and conversion of an assay to a semi-automated or fully automated system using robotics will typically not necessitate full revalidation of the assay. Rather, a methods comparison study may be done to determine if these minor modifications to the assay protocol will affect the test results. Consult Chapter 2.2.8 *Comparability of assays after minor changes in a validated test method* for statistical approaches to assay precision in the face of technical modifications.

In general, these approaches require the use of three reference samples, a negative and a low and high positive. Again these samples may be either natural or prepared. The important point to re-iterate here is that the same reference samples that were used in the developmental stages of the assay may be used to assess modifications after the method has been put into routine diagnostic use. This provides a higher level of confidence assessing potential impacts because the performance characteristics of these reference samples have been well characterised. At the very least, if new reference samples are to be used, they should be selected or prepared using the same criteria or preparation procedures established for previous materials. Again this enhances the continuity of evidence.

6. Reagent replacement (WOAH Validation Standard, Section B.5.2.3)

When a reagent such as a process control sample is nearing depletion, it is essential to prepare and repeatedly test a replacement before such a control is depleted. The prospective replacement should be included in multiple runs of the assay in parallel with the original control to establish their proportional relationship. It is important to change only one control reagent at a time to avoid the compound problem of evaluating more than one variable.

Again, it cannot be over-emphasised that any replacement reference reagent should be selected or prepared using the same criteria or preparation procedures established for previous materials. Again this enhances the continuity of evidence and confidence in the assay.

B. GROUP B

1. Analytical specificity (WOAH Validation Standard, Section B.1.2)

Analytical specificity (ASp) is the degree to which the assay distinguishes between the target analyte and other components that may be detected in the assay. This is a relatively broad definition that is often not well understood. ASp may be broken down into different elements as described below.

The choice of reference samples that are required to assess ASp is highly dependent on the specific purpose or application that was originally envisaged at the development stage of the assay. Assessment of ASp is a crucial element in proof of concept and verification of fitness for purpose.

An important element is the extent to which a method can accurately detect and or quantify the targeted analyte in the milieu of nucleic acids, proteins and/or antibodies in the test matrix. This is sometimes termed 'selectivity'. An example is the use of reference samples for tests that are designed to differentiate infected from vaccinated animals (DIVA tests).

Reference samples need to be selected and tested from i) non-infected/non-vaccinated, ii) non-infected/vaccinated, iii) infected/non-vaccinated, and iv) infected/vaccinated animals. These samples may be collected under field conditions but it is important that an accurate history be collected, ideally with respect to the animals, but at least to the herds involved, including vaccination practices and disease occurrences. Alternatively, it may be necessary to produce this material in experiments like those described in Section A.2.2 of this chapter, but including a combination of experimentally vaccinated and challenged animals. It is important to avoid use of the vaccine as capture antigen in the assay (e.g. indirect enzyme-linked immunosorbent assay [I-ELISA]), because carrier proteins in the vaccine may stimulate non-specific antibody responses in vaccinated animals that may be detected in ELISA leading to false positives in the assay. Similarly to the comparative approach described above with respect to ASe, at least five animals in each group should be considered. For smaller host species, this number may need to be increased in order to collect sufficient reference material. Depending on the DIVA test, a single experiment could be designed to assess aspects of both ASe and ASp.

A second element, sometimes termed 'exclusivity', is the capacity of the assay to detect an analyte or genomic sequence that is unique to a targeted organism, and excludes all other other known organisms that are potentially cross-reactive. This is especially true in serological assays where there are many examples of antigens expressed by other organisms that are capable of eliciting cross-reacting antibody. An attempt should be made to obtain reference samples from documented cases of infections and/or organisms that may be cross-reactive. Depending on the type of assay, these reference materials may represent the organism itself, host-derived samples, or genomic sequences. A profile for the exclusivity of the assay should be established, and expanded on a continual basis as potentially cross-reactive organisms arise.

Thirdly, a critical design consideration relates to the capacity of an assay to detect one or several strains or serovars of a species, several species of a genus, or a similar grouping of closely related organisms or antibodies. This defines the scope of detection and thus the fitness for purpose. Reference samples are required to define the scope of the assay. If for example an assay is developed as a screening test to detect all known genotypes or serotypes of a virus, then reference samples from each representative type should be tested. As new lineages or serotype variants arise, they too should be tested as part of the test profile, which should be updated on an ongoing basis.

2. Analytical accuracy of adjunct tests (WOAH Validation Standard, Section B.1.4)

Some test methods or procedures are solely analytical tools and are usually applied to further characterise an analyte that has been detected in a primary assay, for example assays like virus neutralisation tests used to type an isolated virus or characterise an antibody response. Such adjunct tests must be validated for analytical performance characteristics, but differ from routine diagnostic tests because they do not require validation for diagnostic performance characteristics. The analytical accuracy of these tests is often dependant on the use of reference reagents. These reagents, whether they are antibody for typing strains of organisms or reference strains of the organism, etc., should be thoroughly documented, as required for any other reference material, with respect to their source, identity and performance characteristics.

C. GROUP C

Reference samples in Group C may be used for a number of purposes. In the initial development stages, they may be used in the assessment of assay repeatability and both preliminary reproducibility in Stage 1 and the more in depth assessment of reproducibility in Stage 3 of the Validation Pathway. However, these samples have a number of other potential uses once the assay is transferred to the diagnostic laboratory. They may be used as panels for training and qualifying of analysts, and for assessing laboratory proficiency in external ring testing programmes. Ideally, 20 or more individual samples should be prepared in large volumes. About a quarter (25%) should be negative samples and the remainder (75%) should represent a collection of positives spanning the operating range of the assay. They should be aliquoted into individual tubes in sufficient volumes for single use only and stored for long term use. The number of aliquots of each that will be required will depend on how many laboratories will be using the assay on a routine diagnostic basis and how often proficiency testing is anticipated. Ideally, they should be prepared in an inexhaustible quantity, but this is seldom feasible. At a minimum, several hundred or more aliquots of each should be prepared at a time if the assay is intended for use in multiple laboratories. This allows assessment of laboratory proficiency by testing the same sample over many testing intervals – a useful means of detecting systematic error (bias) that may creep into long term use of an assay.

These samples may be natural or prepared from either single or pooled starting material. The intent is that they should mimic as closely as possible a true test sample. Because mass storage is always a problem, it may be necessary to store these materials in bulk and prepare working aliquots from time to time. However, if storage space is available, it is preferable to prepare and store large numbers of aliquots at one time because bulk quantities of analyte, undergoing freeze–thaw cycles to prepare a few aliquots at a time, may be subject to degradation. Because this type of reference material is consumed at a fairly high rate, they will need to be replaced or replenished on a continual basis. As potential replacement material is identified during routine testing or during outbreaks, it is advisable to work with field counterparts to obtain bulk reference material and store it for future use. Alternatively, it may be necessary to produce this material in experiments like those described in Section A.2.2 of this chapter. Similar to the comparative approach described above with respect to ASe, at least five animals in each group should be considered. For smaller host species, this number may need to be increased in order to collect sufficient reference material.

1. Repeatability (WOAH Validation Standard, Section B.1.1) and Preliminary reproducibility (WOAH Validation Standard, Section B.2.6)

Repeatability is the level of agreement between results of replicates of a sample both within and between runs of the same test method in a given laboratory. Repeatability is estimated by evaluating variation in results of replicates from a minimum of three (preferably five) samples representing analyte activity within the operating range of the assay. Consult Chapter 2.2.4 *Measurement uncertainty* for statistical approaches for measures of uncertainty for assessments of repeatability.

Reproducibility is the ability of a test method to provide consistent results, as determined by estimates of precision, when applied to aliquots of the same samples tested in different laboratories. However, preliminary reproducibility estimates of the candidate assay should be determined during developmental stages. A small panel of three (but preferably five) representing negative and both low and high positives, like those described above, would be adequate. This type of panel could also be used for a limited evaluation of reproducibility to enhance provisional acceptance status for the assay. The test method is usually assessed in one or more laboratories with a high level experience and proficiency in assays similar to the candidate assay. The panel of 'blind' samples is evaluated using the candidate assay in each of these laboratories, using the same protocol, same reagents and comparable equipment. This is a scaled-down version of Stage 3 of assay validation. Consult Chapter 2.2.4 for further explanation of the topic and its application.

2. Reproducibility (WOAH Validation Standard, Section B.3)

Reproducibility is an important measure of the precision of an assay when used in a cross-section of laboratories located in distinct or different regions or countries using the identical assay (protocol, reagents and controls). As the number of laboratories increases, so does the number of variables encountered with respect to laboratory environments, equipment differences and technical expertise. These studies are a measure of an assay's capacity to remain unaffected by substantial changes or substitutions in test conditions anticipated in multi-laboratory use (e.g. shipping conditions, technology transfer, reagents batches, equipment, testing platforms and/or environments). Each of at least three laboratories should test the same panel of 'blind' samples containing a minimum of 20 samples, representing negative and a range of positive samples. If selected negative and/or

positive samples in the panel are duplicated, within-laboratory repeatability estimates may be augmented by replicate testing of these samples when used in the reproducibility studies.

3. Proficiency testing (WOAH Validation Standard, Section B.5.1)

A validated assay in routine use in multiple laboratories needs to be continually monitored to ensure uniform performance and provide overall confidence in test results. This is assessed through external quality assurance programmes. Proficiency testing is one measure of laboratory competence derived by means of an inter-laboratory comparison; implied is that participating laboratories are using the same (or similar) test methods, reagents and controls. Results are usually expressed qualitatively, i.e. either negative or positive to determine pass/fail criteria. However, for single dilution assays, semi-quantitative results provide additional data for assessment of non-random error among the participating laboratories.

Proficiency testing programmes are varied depending on the type of assay in use. For single dilution type assays, panel sizes also vary but a minimum of five samples, representing negative and both low and high positives, like those described above, would be adequate. Proficiency testing is not unlike a continuous form of reproducibility assessment. However, reproducibility, by definition, is a measure of the assay's performance in multiple laboratories; whereas proficiency testing is an assessment of laboratory competence in the performance of an established and validated assay. Measurements of precision can be estimated for both the reproducibility and repeatability data if replicates of the same reference sample are included in this 'blind' panel. Consult Chapter 2.2.4 for further explanation of the topic and its application.

D. GROUP D

Reference samples in Group D differ from the previous Groups in that each sample in the panel should be from a different individual animal. As indicated in Chapter 2.2.8, experimental challenge studies often include repeated sampling of individual animals to determine the progression of disease, but this is a different objective than comparing performance characteristics that would be associated with diagnostic sensitivity (DSe) and diagnostic specificity (DSP) of a test method. Serially drawn samples, taken on different days from the same animal, cannot be used as representative of individual animals in populations targeted by the assay, because such samples violate the rule of independence of samples required for such studies.

Care must be taken in choosing the reference samples and the standard (independent) method used in this type of comparison to ensure that the analytes being detected (if different) demonstrate the same type of pathogenic profile in terms of time of appearance after exposure to the infectious agent, and relative abundance in the test samples chosen.

1. Standard method comparison and provisional recognition (WOAH Validation Standard, Section B.2.6)

There are situations where it is not possible or desirable to fulfil Stage 2 of the Validation Pathway because appropriate samples from the target population are scarce and animals are difficult to access (such as for exotic diseases). However, a small but select panel of highly characterised test samples representing the range of analyte concentration should be run in parallel in the candidate assay method and by an WOAH standard method, as published in the WOAH *Manuals*. If the methods are deemed to be comparable (Chapter 2.2.8), and depending on the intended application of the assay, the choice may be made that further diagnostic validation is not required. For example, if the intended application is for screening of imported animals or animal products for exotic pathogens or confirmation of clinical signs, full validation beyond a test method comparison may not be feasible or warranted.

Experience has shown that the greatest obstacle to continuing through Stage 2 of the Validation Pathway is the number of defined samples required to estimate diagnostic performance parameters with a high degree of certainty (WOAH Validation Standard, Section B.2). In some cases, provisional recognition by international, national or local authorities may be granted for an assay that has not been completely evaluated past analytical stages. The different rationales for provisional acceptance are well explained in the WOAH Validation Standard. In all cases however, sound evidence must exist for comparative estimates of DSp and DSe based on a small select panel of well-characterised samples containing the targeted analyte.

Ideally, for both comparison with a standard method or provisional recognition, a panel of, for example, 60 samples could be assembled to ensure sufficient sample size for statistical analysis of the resulting data. This would include 30 'true' negatives and 30 'true' positives. Wherever possible, the positives should reflect the range of analyte concentrations or activities expected in the target population. As mentioned above, each sample in this panel must represent an individual animal. Consult Chapter 2.2.5 for statistical approaches to determining methods comparability using diagnostic samples.

2. Biological modifications (WOAH Validation Standard, Section B.5.2.2)

There may be situations where changes to some of the biologicals used in the assay may be necessary and/or warranted. This may include changes to reagents themselves or a change to a different type of specimen which contains the same analyte as targeted in the original validated assay (e.g. from serum to saliva). At the very least, all of the analytical criteria of the validation pathway must be re-assessed before proceeding. If the analytical requisites are met, the remaining question relates to whether or not a full diagnostic validation is required. A similar approach to the above using a panel of 60 individual reference samples may be considered. However, in this case the original test method would be considered as the standard (independent) test and the modified method would be considered the candidate. Consult Chapter.2.2.5 for statistical approaches to determining methods comparability using diagnostic samples.

E. GROUP E

Reference animals and reference samples in this Group E are well described in the WOAH Validation Standard, Section B.2.1). However, there are a few points that are worth re-iterating here.

1. 'Gold standard'[2] – diagnostic specificity and diagnostic sensitivity (WOAH Validation Standard, Section B.2.1)

For conventional estimates of DSp, negative reference samples refer to true negative samples, from animals that have had no possible infection or exposure to the agent. In some situations, where the disease has never been reported in a country or limited to certain regions of a country, identification of true negative reference samples is usually not a problem. However, where the disease is endemic, samples such as these may be difficult to locate. It is often possible to obtain these samples from regions within a large country or perhaps different countries where the disease in question has either been eradicated or has never had the disease in question.

Again for conventional estimates of DSe, positive reference samples refer to true positives. Care must be taken to ensure that the sample population is representative of the population that will be the target of the validated assay. It is generally problematic to find sufficient numbers of true positive reference animals, as determined by isolation of the organism. It may be necessary to resort to samples from animals that have been tested by a combination of methods that unequivocally classify animals as infected/exposed as discussed in the WOAH Validation Standard.

The important point here is that all samples, irrespective of origin, must be documented as they would for any other reference sample so as unequivocally to classify animals as infected or exposed dependent on the fitness for purpose and proposed use of the test. As mentioned in Section A of this chapter, all reference samples should be well characterised. This includes documentation on both the pathogen and donor host. For pathogens, this may include details related to strain, serotype, genotype, lineage, etc. The source of the host material should be well described with respect to species, breed, age, sex, reproductive status, vaccination history, herd history, etc. Wherever possible, the phase of infection should be noted. This could include details related clinical signs, antibody profiles, pathogen load or shedding, etc. In some cases, experimental infection/exposure may be the only viable option for the production of reference material (see the WOAH Validation Standard, Section B.2.3). In this case, all of the above and the experimental protocol should be detailed.

Particularly relevant to these reference samples, the tests that are used to determine their so called 'true' disease/infection status need to be well documented in order to assess potential errors in estimates that may be carried over into the estimates for the candidate assay. Indeed, when using imperfect standard assays to define

2 The term "Gold Standard" is limited to a perfect reference standard as described in the WOAH Validation Standard, Section B.2.1.2, and Chapter 2.2.5, Introduction and Figure 1.

reference animal or sample status, the DSe and DSp performance estimates of the candidate assay may be flawed and often overestimated. Consult Chapter 2.2.5 for statistical considerations.

F. GROUP F

1. Animals of unknown status – diagnostic specificity and diagnostic sensitivity (WOAH Validation Standard, Section B.2.2)

Latent-class models are introduced in the WOAH Validation Standard. They do not rely on the assumption of a perfect reference (standard or independent) test but rather estimate the accuracy of the candidate test and the reference standard with the combined test results. Because these statistical models are complex and require critical assumptions, statistical assistance should be sought to help guide the analysis and describe the sampling from the target population(s), the characteristics of other tests included in the analysis, the appropriate choice of model and the estimation methods based on peer-reviewed literature. Consult Chapter 2.2.5 for statistical considerations.

Reference populations, not individual reference samples, used in latent-class studies need to be well described. This includes documentation on both the pathogen and donor host. For pathogens, this may include details related to strain, serotype, genotype, lineage, etc., that may be circulating in the population. The source of the host material should be well described with respect to species, breed, age, sex, reproductive status, vaccination history, herd history, etc. Wherever possible, the phase of infection in the populations should be noted with respect to morbidity or mortality events, recovery, etc.

As a special note, if latent class models are to be used to ascribe estimates of DSe and DSP and include multiple laboratories in the design, it is possible to incorporate an assessment of reproducibility into the assessment. As stated above, statistical advice should be sought in this respect.

CHAPTER 2.2.8.

COMPARABILITY OF ASSAYS AFTER CHANGES IN A VALIDATED TEST METHOD

INTRODUCTION

There are many reasons why validated assays undergo changes over time. Replacement of depleted reagents is probably the most common example of a minor change to a validated assay (see C*hapter 1.1.6* Validation of diagnostic assays for infectious diseases of terrestrial animals*, Figure 1, Assay development and validation pathways*). *Small changes may be driven by: the availability of less expensive or better reagents, e.g. nucleic acid extraction reagents for molecular tests; the need for improved standardisation, e.g. changing from operator-coated to pre-coated enzyme-linked immunosorbent assay* (*ELISA*) *plates; increased throughput requirements, e.g. manual versus robotic handling, etc. Such minor changes usually require an experimental study to assess whether the performance characteristics of the validated assay are still comparable with the new procedure* (*Table 1, Figure 1*). *There are other important variables outside of the assay that may require verification, such as the nature of the target population, the species and the specimen. For example, experienced laboratory diagnosticians would be cautious about applying a competitive brucellosis antibody ELISA to cattle in Latin America if it had been validated specifically for cattle in Canada* (*Gall* et al., *1998*). *Assays are often applied to a species other than that for which they had been originally validated, e.g. domestic chickens versus wild birds or beef versus dairy cattle. Other changes included the use of different test specimens, e.g. tracheal swabs versus cloacal swabs from birds for diagnosis of avian influenza using molecular assays. Under these circumstances, a verification study would be necessary to validate the performance characteristics of the test under the new circumstances.*

Controversy exists about what constitutes a "minor" and a "major" change for a diagnostic assay. There are some changes that are regarded as major because the biological basis of the assay is fundamentally altered, for example, evolutionary changes or mutations in the nucleic acid make-up of a pathogen will require adjustments to be primers and probes. Similarly, a change from an indirect to a competitive ELISA format using a highly specific monoclonal antibody is considered a major change that would warrant complete re-validation of the assay. Table 1 provides some examples of minor and major changes that are found frequently in the use of antibody and nucleic acid detection tests. Rigorous and well designed comparability studies provide an objective assessment of whether the assay, when used with a minor change, is as comparable to, and fit for the intended use, as the validated assay. The outcome of the experimental study will determine whether or not the candidate assay requires full re-validation and consequently whether or not it can be used with confidence.

Validation is a process that determines the fitness of an assay, which has been properly developed, optimised and standardised, for an intended purpose.

Verification represents evidence that the performance characteristics, e.g. accuracy and precision of a validated assay, are comparable when used in another laboratory.

Comparability is the preferred term when performance characteristics of a new test, which has undergone a minor change, are as good as those of a validated test within statistically defined limits.

Equivalence or equivalency has historically been used in some diagnostic laboratories for comparability studies. However, the term implies a more stringent requirement than fitness for intended use and also has a specific statistical meaning. For these reasons, the term is not used in this chapter.

A. SETTING UP COMPARISON EXPERIMENTS

Table 1. Examples of change in diagnostic tests

Type of change	Changes in assay	Changes in target population or specimens
Minor	Replacement of depleted reagent, e.g. positive control sample, new batch of antigen, plates, conjugate (ELISA) Change of instrument/platform, e.g. ELISA reader, incubator/shaker, thermocycler (PCR) Change from individually coated to pre-coated ELISA plates Change from manual to robotic handling (ELISA, NAD) Change in nucleic acid extraction procedure (NAD) Use of modified primer(s) or probe (partial substitution of sequences, e.g. degeneracy) Modified PCR reaction conditions using the same primers(s) and probe(s) Addition of an extra probe within the amplified region Change in probe chemistry (NAD)	
Major	Substitution of a recombinant antigen for a cell culture-derived antigen in an ELISA Change from an indirect to a competitive ELISA using a specific monoclonal antibody Change of primers and probes for different targets in different regions of the same or different gens (NAD)	Different species, e.g. cattle versus buffalo, domestic chicken versus wild birds Different specimen types, e.g. tracheal versus cloacal swabs, blood versus semen, different tissues or organs

ELISA = enzyme-linked immunosorbent assay; PCR = polymerase chain reaction; NAD = nucleic acid detection (tests);

When setting up a comparison experiment, the procedure should be guided by the purpose of the assay (Figure 1, step 1). For example, screening assays require high diagnostic sensitivity, and it is important to compare the limit of detection. In such a case a suitable dilution range and the number of replicates of a control sample have to be determined. A sufficient quantity of well characterised control sample material needs to be produced, aliquoted and stored appropriately.

If the objective is to assess and compare repeatability it is necessary to run well characterised replicates of control samples of different analyte concentrations spanning the expected operating range of the assay, e.g. a high, medium and low analyte concentration. For practical purposes, the example given in this chapter only uses a weak-positive control sample. It is good practice to visually inspect correlation of results between both methods. For example, a scatter diagram and a histogram are easily performed and provide immediate information about the type of correlation and distribution of data (Figures 2 and 3). Basic statistics help to set upper and lower limits and evaluate results, for example for limit of detection or repeatability (Tables 2 and 3). A more sophisticated approach to comparing and analysing results from a comparison study is a Bland–Altman plot (Figure 4 and Table 4).

Figure 5 is an example of how to increase the efficiency of comparison experiments by assessing different parameters simultaneously on a single plate, e.g. assessing analytical sensitivity using dilution steps of a target analyte in triplicate, followed by assessing analytical specificity using a number of negative samples (which do not carry the target analyte), and finally assessing analytical sensitivity using a number of samples from infected animals with different analyte concentrations. The use of replicates in the same run and between runs allows estimation of repeatability (Figure 5 and 6).

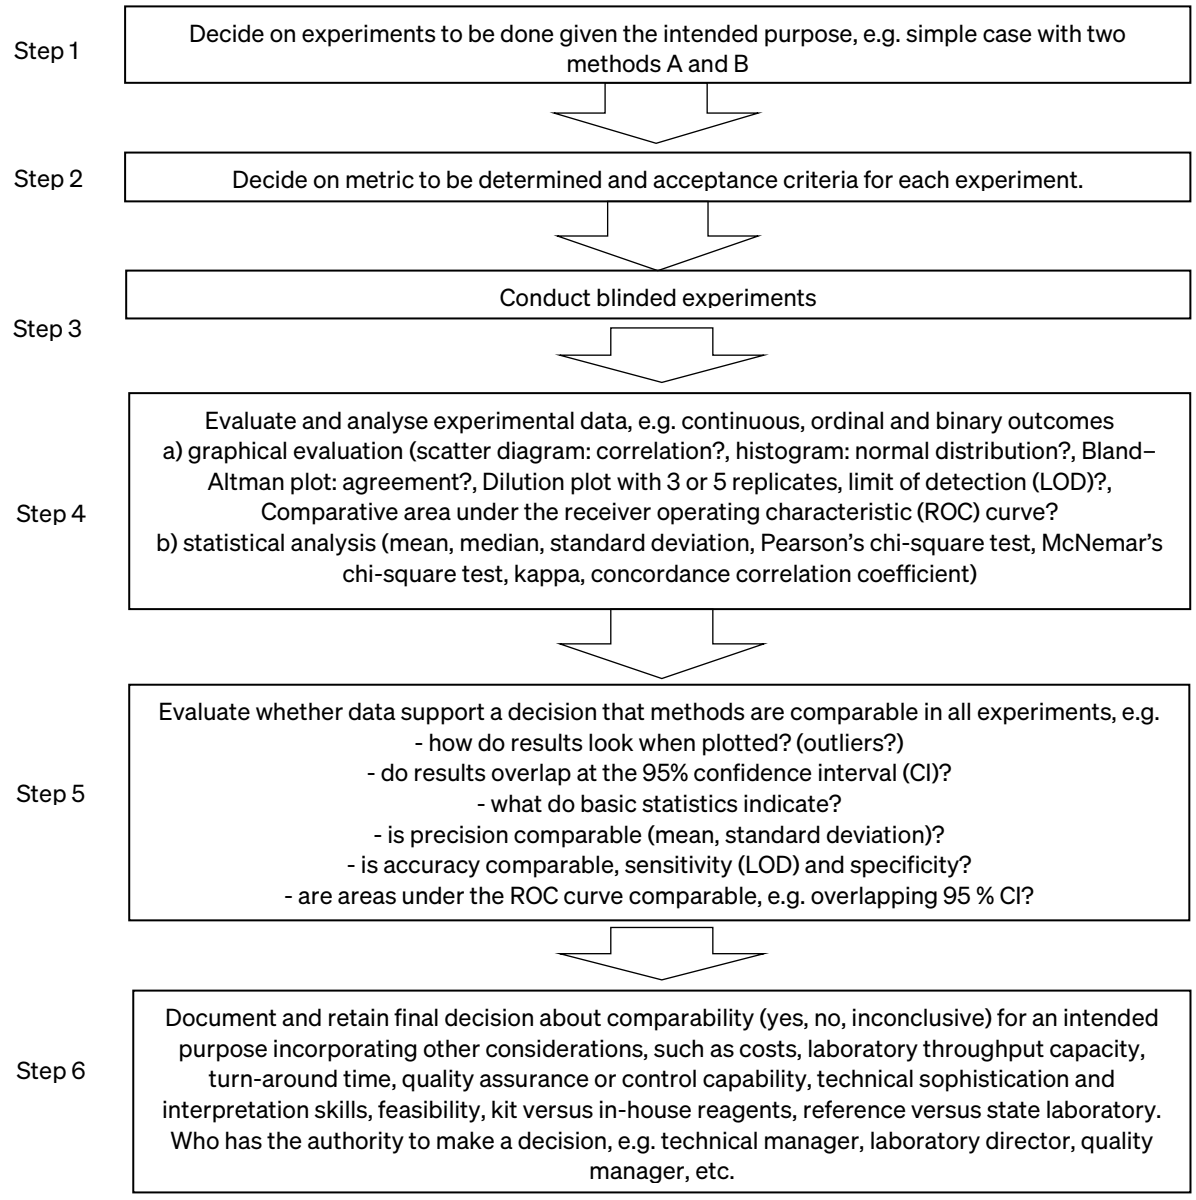
It is important to agree on acceptance criteria to evaluate the outcome of the experiment (Figure 1, step 2), e.g. confidence intervals can be asymmetric to allow for better performance of a novel assay. In this chapter a conservative 95% confidence estimate is regarded as acceptable for a limit of detection experiment (Figures 6 and 7). For comparison of repeatability, the mean and standard deviation (SD) or direct test results plus and minus

a given range can be used as acceptance criteria (Tables 3 and 4 and Figure 4). Results from a panel of infected and non-infected individuals provide information about comparative diagnostic sensitivity and specificity (Figure 8 and Tables 5 and 6).

Data used in Figures 2, 3 and 4 and Tables 2, 3 and 4 were produced using results from a repeatedly tested weak positive control sample in two TaqMan assays that target the M (M1 assay) and N (N1 assay) genes of Hendra virus.

Data for LOD experiments and plate layout in Figure 5, 6 and 7 are fictive. Data for ROC curves in Figure 8 and Tables 5 and 6 are taken from comparison experiments of different Influenza ELISAs in pigs.

Fig. 1. Factors to be considered for comparability studies of diagnostic tests.

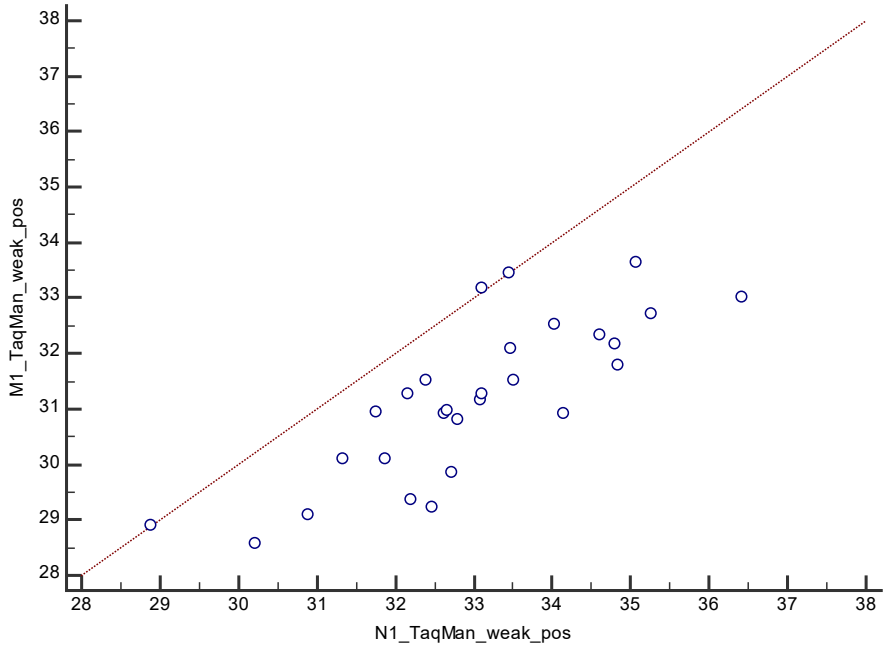


This chapter provides an overview of different approaches to the design of experiments and interpretation of results from assay comparison studies, e.g. analytical (limit of detection) and diagnostic sensitivity, analytical and diagnostic specificity, and repeatability. There are many fundamentally different tests but the examples provided stem from or refer to experiments with nucleic acid detection (NAD) and enzyme-linked immunosorbent assays (ELISAs). It can be assumed that the principles provided in this chapter are equally applicable to other tests.

B. VISUAL INSPECTION

A **Scatter diagram** is useful for visually evaluating the correlation between both methods initially, e.g. is the relationship linear or logarithmic? Are there outliers or missing values or artefacts? The example in Figure 2 uses results from a repeatedly tested weak positive control sample from two TaqMan assays that target the M (M1 assay) and N (N1 assay) genes of Hendra virus. Results show that data for the N1 assay are shifted to the lower right compared with the M1 assay, which indicates consistently higher values for N1 than for M1 assay. However the scatter diagram does not provide information about the agreement of the two tests. There is one exception to this rule, if all results for both tests would fall along the 45% diagonal line, the agreement would be 100%. In Figure 2 only three results fall along the diagonal line. In this paper we define agreement as a set of values of a candidate test that fall within the 95% CI of the results of the established test after repeated runs of the same well characterised control sample. Correlation measures the strength of the relation between measurements from these tests and is expressed as p value.

Fig. 2. Scatter diagram of a weak positive control sample after being tested 28 times in two different Hendra TaqMan assays, M1 and N1 (results expressed as cycle threshold [Ct] values).



Further analysis of results is given in Table 2 below, where r (correlation coefficient) = 0.8 and indicates a strong, positive correlation between the two methods. $p < 0.0001$ indicates that the probability that this association is due to chance is very low and the 95%CI (confidence interval) indicates that when these methods are used on a similar subject and under similar conditions, we are 95% confident that the true unknown value of r lies between 0.61 and 0.9.

Table 2. Statistical analysis of a weak positive control sample after being tested 28 times in two Hendra TaqMan assays, M1 and N1

Variable Y	M1 TaqMan weak positive
Variable X	N1 TaqMan weak positive
Sample size	28
Correlation coefficient r	0.8015
Significance level	$p<0.0001$
95% confidence interval for r	0.6112 to 0.9042

A **histogram**, where skewing to the left or to the right or other relevant characteristics such as a bimodal distribution would be detected is shown Figure 3.

Fig. 3. Histogram of a weak positive control sample after being tested 28 times in two Hendra TaqMan assays, M1 and N1 (results expressed as cycle threshold [Ct] values).

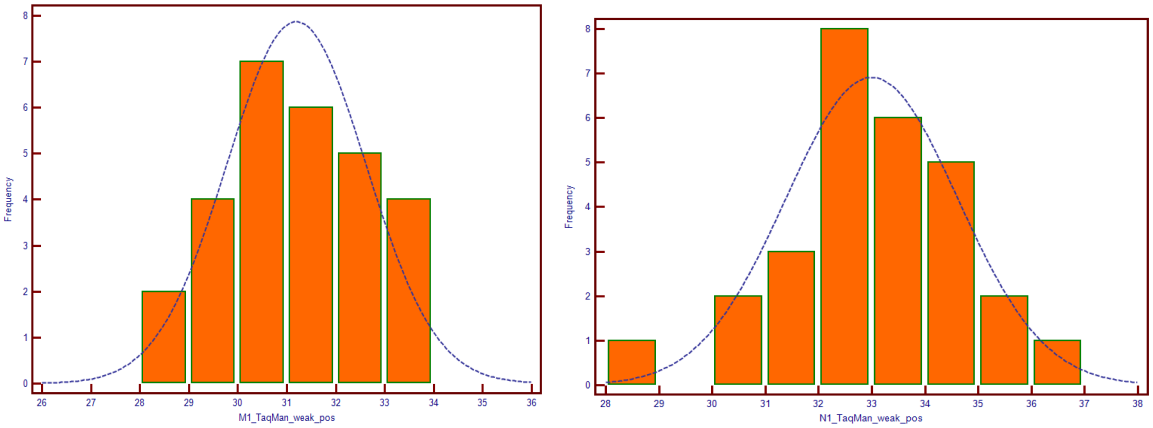


Table 3. Statistical analysis of a weak positive control sample after being tested 28 times in two Hendra TaqMan assays, M1 and N1 (results expressed as cycle threshold [Ct] values)

	M1 Taqman weak positive	**N1 Taqman weak positive**
Sample size	28	28
Lowest value	28.58	28.88
Highest value	33.63	36.42
Mean	31.19	33.00
Median	31.22	32.94
Standard deviation (SD)	1.42	1.62

C. REPEATABILITY

Assay variation can be assessed using replicates of an internal control sample when used in sequential runs over time. In this example, repeatability was compared for two different Hendra TaqMan assays targeting the N and M genes using a weak-positive internal control sample after 28 runs by the same operator on 14 days and during an 18-day period. Cycle threshold (Ct) results were summarised as the mean and standard deviation (SD) in Table 3.

Because the estimates are based on a single control sample, no formal comparison is necessary. Rather, if the predefined acceptance criteria for both assays were, e.g. 2 to 3 SDs or ± 2 to 3 Ct values then both assays would be considered comparable.

D. BLAND–ALTMAN PLOT

A very efficient way to simultaneously display and analyse results from a comparison study where 2 different measurements are made on the each sample (so called matched-pairs design) is a Tukey mean difference plot (Bland & Altman, 1999, 2007; Kozk & Wnuk, 2014). The plot is useful for revealing a relationship between the differences and the averages, evaluating any systematic biases and identifying possible outliers. Average Ct values obtained with methods A (M1 TaqMan assay) and B (N1 TaqMan assay) across a range of results are plotted along the x-axis and differences in the mean values, e.g. A minus B, are displayed on the y-axis (Figure 4, Table 4). In the example, the M1 TaqMan is compared with N1 TaqMan using results from a weak positive control sample after 28 runs. All differences are negative because the mean values for N1 TaqMan (Ct 33) are higher than M1

TaqMan (31.99) (Table 3). Subtracting N1 from M1 reveals that almost all values are negative, which indicates a systematic bias, e.g. the average difference between N1 and M1 was –1.81 (bias). Horizontal lines are drawn at the mean difference (–1.81), and at the limits of agreement, which are defined as the mean difference plus and minus 1.96 times the standard deviation of the differences, which, expressed in average Ct differences, are 0.1 to –3.71. Results in Table 4 show that the 95% CI for the mean difference (–2.18 to –1.43) exclude zero and hence, it cannot be concluded that the two methods are comparable. Adjustment of the cut-off could help to counterbalance this apparent systematic bias between both methods after corroborating these findings with larger sample numbers and over the range of expected results.

One measurement is made by each method on each sample (matched-pairs design) to compare repeatability between the two methods over the measurement range, e.g. for competitive antibody ELISAs it is known that variation increases with the decrease of the analyte concentration in the sample. A negative or weak-positive control sample may have significantly higher variation than high-positive control samples. Figure 4 shows three results that lie along the line for the 0 value, e.g. the line where results for both tests are identical because the difference is zero. These are the same results that fall on the diagonal line of equality in the scatter diagram in Figure 2 at values of 28.9, 33.10 and 33.45 for both assays.

Fig. 4. Bland–Altman plot showing differences of cycle threshold (Ct) values in two Hendra TaqMan assays, M1 and N1 for a weak-positive control sample after being tested 28 times.

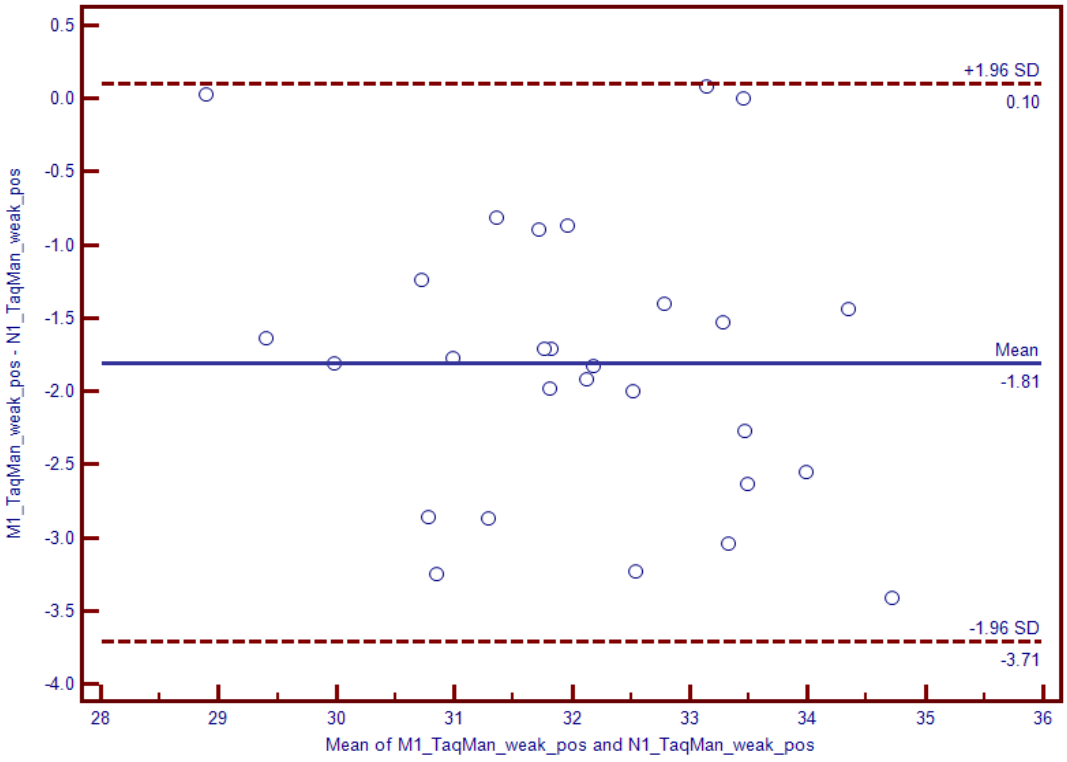

Table 4. Statistical analysis for Bland–Altman plot

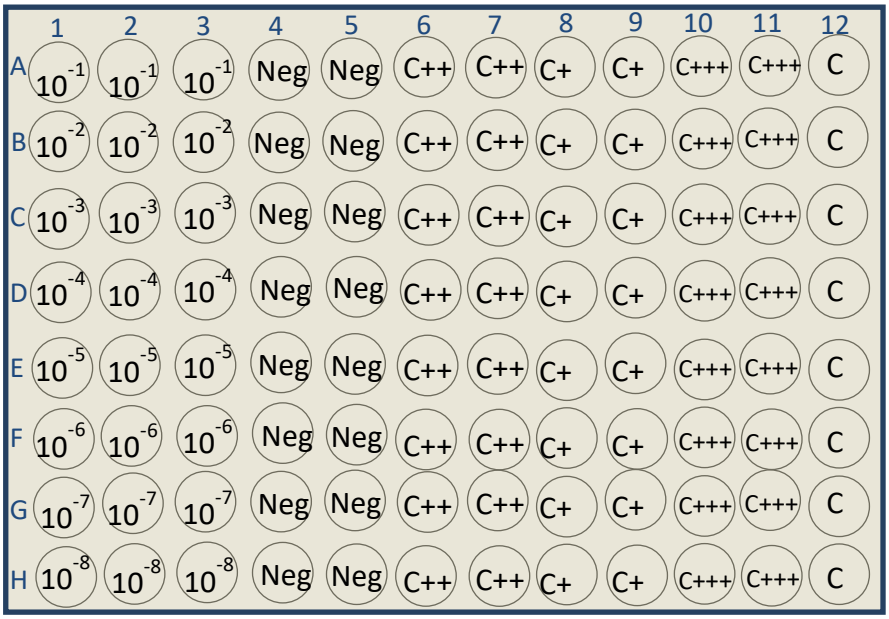
Method A	M1 TaqMan weak positive
Method B	N1 TaqMan weak positive
Differences	
Sample size	28
Arithmetic mean	–1.8054
95% CI	–2.1831 to –1.4276
Standard deviation	0.9741

E. LIMIT OF DETECTION (LOD) EXPERIMENT

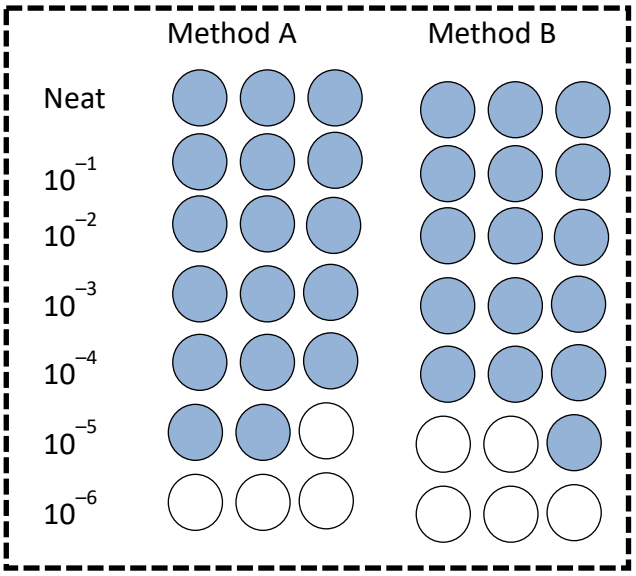
An example of a plate layout for a comparability study of a molecular test is given in Figure 5. Limit of detection (three replicates of positive samples in a dilution series from 10^{-1} to 10^{-8} [analytical sensitivity]), diagnostic specificity (negative diagnostic samples from non-infected animals or animals that have been infected with a non-target pathogen [Neg] tested in duplicate), diagnostic sensitivity (samples from field infected animals of different activity, e.g. extremely high positive [C+++], very high positive [C++], high positive [C+] and positive [C] tested in duplicate), and repeatability are assessed. Cross-contamination can be also evaluated as strong positive samples are placed next to negative samples.

Fig. 5. Layout of 96-well plate to assess analytical Se, diagnostic Se and Sp and repeatability.



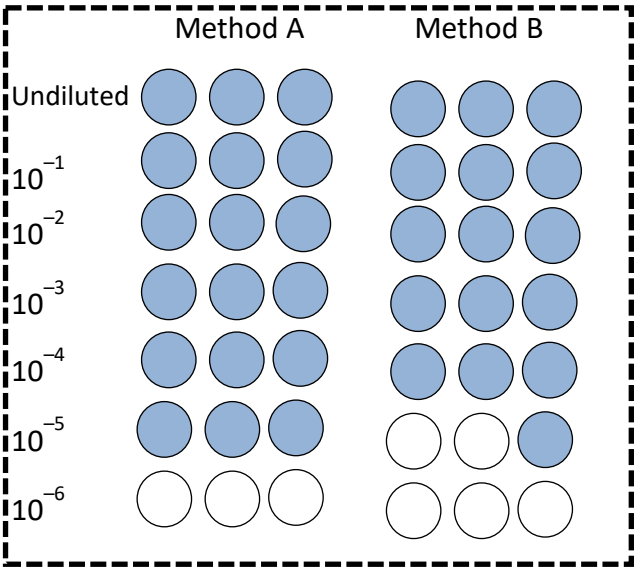
The limit of detection (LOD) is a measure of the analytical sensitivity (ASe) of an assay. The LOD is the estimated amount of analyte in a specified matrix that would produce a positive result at least a specified per cent of the time. Figures 6 and 7 represent hypothetical results of a LOD experiment. For example, in a titration using tenfold dilutions all replicates at all dilutions might show either 100% or 0% response. There are two choices at that point. The last dilution showing 100% response may be accepted as a conservative estimate of the lower limit of detection. A more accurate estimate may be obtained by a second stage experiment using narrower intervals in the dilution scheme focusing on the region between 100% and 0%. The first step is to produce, aliquot and blind a sufficient number of samples to carry out the experiment. The second step is to produce a set of analyte dilutions, preferably using sample matrix as diluent, rather than buffer, which reflect the measurement range of the method, e.g. in a tenfold dilution series, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}. Practical examples often use 3–5 replicates per dilution step. Using a conservative estimate of 100% (all 3 wells at the highest dilution dark = positive) Figures 6 and 7 show comparable and non-comparable outcomes, respectively. Method A represents the validated and method B the new method.

Fig. 6. Example of a limit of detection (LOD) experiment with an acceptable outcome.



In Figure 6 at the 10^{-4} dilution all replicates from method A and method B are positive (blue). At the 10^{-5} dilution only two out of three wells are positive for method A and one out of three is positive for method B. As the limit of detection is defined as the dilution where all wells must be positive results from the 10^{-5} dilution downwards are not considered for comparability. Applying these criteria the limit of detection in Figure 6 is the same for methods A and B and therefore the two methods can be regarded as comparable.

Fig. 7. Example of a limit of detection (LOD) experiment with a non-acceptable outcome.



In Figure 7 the highest dilution of all three replicates is at 10^{-5} for method A. In contrast the highest dilution where all three replicates are still positive for method B is at 10^{-4}. Consequently, the limits of detection of methods A and B cannot be considered comparable if a single log dilution is not acceptable. It is advisable to repeat the experiment several times before making a final decision on comparability.

F. COMPARISON OF ROC CURVES

Receiver operating characteristic (ROC) analysis is a powerful method to assess and compare the overall accuracy of a diagnostic test, e.g. diagnostic sensitivity (DSe) and diagnostic specificity (DSp) at different cut-offs of one or more different or modified tests (Greiner *et al.,* 2000). The central measurement is the area under the curve (AUC), e.g. a value of 1 indicates a test with 100% DSe and 100% DSp. In this case there is perfect separation

of the values of the two groups, i.e. there is no overlapping of the distributions and the ROC curve will reach the upper left corner of the plot. In contrast a value of 0.5 indicates no discrimination between infected and non-infected individuals beyond chance; the ROC curve coincides with the diagonal indicating that the test is useless. Values between 0.5 and ≤0.7 can be considered less accurate, from 0.7 to ≤0.9 moderately accurate and from 0.9 to <1 as highly accurate (Greiner *et al.,* 2000).

Figure 8 shows results from four antibody ELISAs for influenza virus in pigs. The serum panel consisted of 168 positive and 77 negative sera using the haemaglutination inhibition as a reference test (*n*=245). When compared on these diagnostic samples the following ranking was established: test 1 (AUC = 0.988), test 4 (AUC = 0.988), test 3 (AUC = 0.929) and test 2 (AUC = 0.814) (Table 5). For this matched pair design experiment the 95% CI for the differences of the Area Under the ROC curve (AUC) can be used as an indicator for statistical significance (Table 6). In summary, the test with the best DSe and DSp and the highest area under the curve (0.988) is test 1. The result of 0.988 means that a randomly selected individual from the positive group has a test value larger than that for a randomly chosen individual from the negative group 99% of the time (Zweig & Campbell, 1993).

Another way to compare results is to evaluate AUC differences. For example for test 1 and 2 the difference between the AUC was 0.0173, for test 1 and test 3 the result was 0.058, for test 1 and 4 the result was 0.00019, for test 2 and 3 the result was 0.1150, for test 2 and 4 the result was 0.174 and for test 3 and 4 the result was 0.0586 (Table 6). The tests with the highest AUCs and smallest difference of AUCs were test 1 and test 4, e.g. both tests had an AUC of 0.988, overlapping 95% CI, the difference between the AUCs was as low as 0.00019 and a *p* value of 0.98 indicated no statistically significant difference at the 5% significance level. Lower AUC values, lack of overlapping 95%CI, significantly increased AUCs and *p* values <0.05 indicated lack of agreement of other test combinations, e.g. 1 vs 3, 1 vs 2, 2 vs 3, 2 vs 4 and 3 vs 4. Test 1 0.964 to 0.997, test 2 0.760 to 0.861, test 3 0.889 to 0.958, test 4 0.965 to 0.997.

More complex comparison studies with tests based on similar diagnostic and biological principles using frequentist and classical statistical approaches have been published (Brocchi *et al.,* 2006; Engel *et al.,* 2008). See also Chapter 2.2.5. *Statistical approaches to validation*.

Fig. 8. Comparison of receiver operating characteristic (ROC) area under the curve (AUC) for four different ELISAs to detect antibodies against influenza virus in pigs.

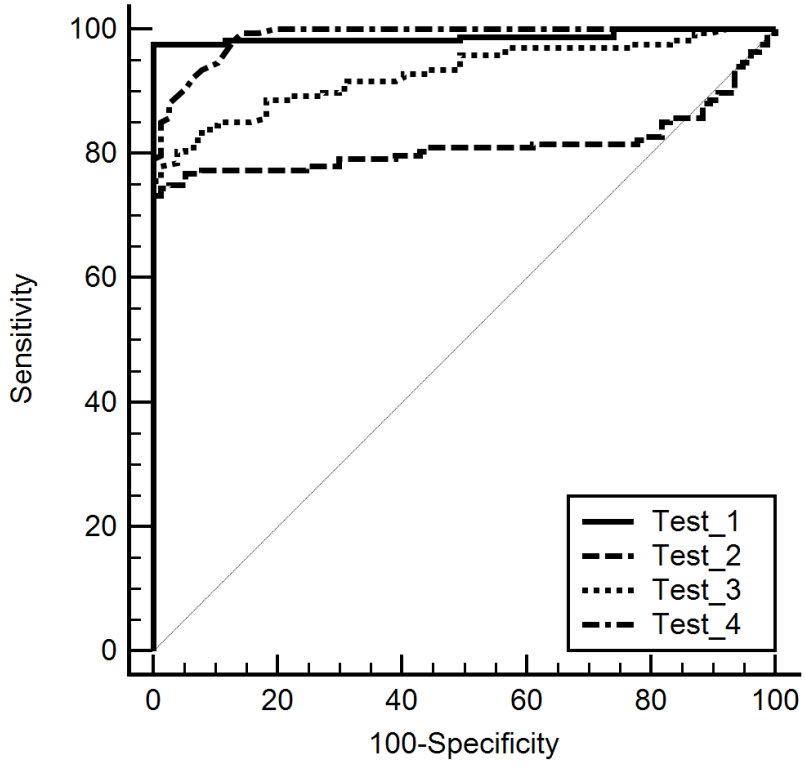


Table 5. Receiver operating characteristic (ROC) comparison of area under the curve (AUC) and p-values for four different ELISAs to detect antibodies against influenza in pigs

Parameter	Test 1	Test 2	Test 3	Test 4
Area under ROC curve	0.988	0.814	0.929	0.988

Table 6. Pairwise comparison of ROC curves

	Test 1 vs 4	Test 1 vs 3	Test 3 vs 4	Test 2 vs 3	Test 1 vs 2	Tetst 2 vs 4
Difference between AUC	0.0002	0.055	0.0589	0.115	0.173	0.174
95% CI	–0.016 to 0.016	0.025 to 0.092	0.027 to 0.090	0.069 to 0.161	0.117 to 0.230	0.118 to 0.229
Significance level	p=0.9808	p =0.0007	p =0.0003	p <0.0001	p <0.0001	p <0.0001

G. DISCUSSION AND CONCLUSIONS

Results from comparison experiments must be evaluated to reach a conclusion as to whether both methods are comparable using statistical analyses and objective assessments to assist with a final decision (NATA, 2013). However, often other criteria such as costs/equipment, throughput capacity, turn-around time, quality assurance capability, technical sophistication, acceptance in regulatory or scientific community and interpretative skills also need to be considered in decision-making (Figure 1, Step 6). It is important to have a process in place, which clarifies who has the authority to make the final decision whether methods are comparable, e.g. technical manager, laboratory director, quality manager.

For example, comparison of two TaqMan assays indicated strong and positive correlation. Repeatability of both methods was comparable when applying 2–3 SD or ± 2–3 Ct. Ct values from a weak positive-control sample were consistently lower for the M1 than for the N1 TaqMan, indicating a slightly superior Se of the M1 assay. If used as a screening test the M1 would be more suitable due to its higher Se. Results were corroborated by testing diagnostic samples from Hendra virus outbreaks between 2011 and 2013 (data not shown). On the other hand having two tests, which target different genes increases the chance of not missing a new variant. In the case of a deadly zoonosis such as Hendra virus this is an important consideration.

Results from the Bland–Altman Plot in Figure 4 and Table 4 show that statistical results sometimes are difficult to interpret, e.g. the 95% CI for the mean difference excludes zero. This might be interpreted as a lack of comparability but change in the cut-off value can be used to compensate for this outcome.

ROC analysis of 4 different swine influenza ELISAs (Figure 8 and Tables 5 and 6) indicated two tests of almost identical DSe and DSp (Tests 1 and 4). At the same time it helps to rank the performance of the other tests. Under these circumstances cost, availability and other criteria will determine the final decision as to which test is the most suitable for a designated purpose.

On the other hand, not all parameters need to be addressed in every method comparison study. For example, an assessment of cross-contamination would be necessary for changes in equipment such as manual vs robotic nucleic acid extraction procedure but not for changing a key reagent, e.g. a different primer or probe. It is good practice to decide on relevant parameters and acceptance/rejection criteria before the experiment. The most relevant question is whether the new test is fit-for-purpose.

It is in the nature of veterinary diagnostic testing to allow for flexibility when it comes to the specification of acceptance limits, e.g. when comparing two different molecular tests it could be that the difference is no more than 1, 2 or 3 Ct in 95% (99%) of tested samples, no more than 10% of the average of the 2 samples in at least 95% (99%) of tested samples, no more than 1, 2, or 3 SD of the samples. It is recommended to consider relevant parameters and limits up front although the qualitative considerations (e.g. cost, ease of testing, rapidity of

results) probably come in at the end. Whatever parameter is chosen as a basic rule the candidate test should on average not be significantly underperforming the validated test.

The data generated and the decision making process for the acceptability of the change should be clearly documented and retained to show an audit trail.

H. DATA ANALYSIS

Data were stored and grouped in Microsoft Excel. Analysis and plotting for scatter diagrams, histograms, data distribution and plotting, Bland Altman Plots, comparison graphs and ROC analysis were performed using MedCalc (MedCalc®, Version 12.4.0.0, 64 bit, Window XP/Vista 7/8, *www.medcalc.org*, Copyright 1993–2013, MedCalc software bvba).

CHAPTER 2.2.8.

COMPARABILITY OF ASSAYS AFTER CHANGES IN A VALIDATED TEST METHOD

INTRODUCTION

There are many reasons why validated assays undergo changes over time. Replacement of depleted reagents is probably the most common example of a minor change to a validated assay (see C*hapter 1.1.6* Validation of diagnostic assays for infectious diseases of terrestrial animals*, Figure 1, Assay development and validation pathways*). *Small changes may be driven by: the availability of less expensive or better reagents, e.g. nucleic acid extraction reagents for molecular tests; the need for improved standardisation, e.g. changing from operator-coated to pre-coated enzyme-linked immunosorbent assay* (*ELISA*) *plates; increased throughput requirements, e.g. manual versus robotic handling, etc. Such minor changes usually require an experimental study to assess whether the performance characteristics of the validated assay are still comparable with the new procedure* (*Table 1, Figure 1*). *There are other important variables outside of the assay that may require verification, such as the nature of the target population, the species and the specimen. For example, experienced laboratory diagnosticians would be cautious about applying a competitive brucellosis antibody ELISA to cattle in Latin America if it had been validated specifically for cattle in Canada* (*Gall* et al., *1998*). *Assays are often applied to a species other than that for which they had been originally validated, e.g. domestic chickens versus wild birds or beef versus dairy cattle. Other changes included the use of different test specimens, e.g. tracheal swabs versus cloacal swabs from birds for diagnosis of avian influenza using molecular assays. Under these circumstances, a verification study would be necessary to validate the performance characteristics of the test under the new circumstances.*

Controversy exists about what constitutes a "minor" and a "major" change for a diagnostic assay. There are some changes that are regarded as major because the biological basis of the assay is fundamentally altered, for example, evolutionary changes or mutations in the nucleic acid make-up of a pathogen will require adjustments to be primers and probes. Similarly, a change from an indirect to a competitive ELISA format using a highly specific monoclonal antibody is considered a major change that would warrant complete re-validation of the assay. Table 1 provides some examples of minor and major changes that are found frequently in the use of antibody and nucleic acid detection tests. Rigorous and well designed comparability studies provide an objective assessment of whether the assay, when used with a minor change, is as comparable to, and fit for the intended use, as the validated assay. The outcome of the experimental study will determine whether or not the candidate assay requires full re-validation and consequently whether or not it can be used with confidence.

Validation is a process that determines the fitness of an assay, which has been properly developed, optimised and standardised, for an intended purpose.

Verification represents evidence that the performance characteristics, e.g. accuracy and precision of a validated assay, are comparable when used in another laboratory.

Comparability is the preferred term when performance characteristics of a new test, which has undergone a minor change, are as good as those of a validated test within statistically defined limits.

Equivalence or equivalency has historically been used in some diagnostic laboratories for comparability studies. However, the term implies a more stringent requirement than fitness for intended use and also has a specific statistical meaning. For these reasons, the term is not used in this chapter.

A. SETTING UP COMPARISON EXPERIMENTS

Table 1. Examples of change in diagnostic tests

Type of change	Changes in assay	Changes in target population or specimens
Minor	Replacement of depleted reagent, e.g. positive control sample, new batch of antigen, plates, conjugate (ELISA) Change of instrument/platform, e.g. ELISA reader, incubator/shaker, thermocycler (PCR) Change from individually coated to pre-coated ELISA plates Change from manual to robotic handling (ELISA, NAD) Change in nucleic acid extraction procedure (NAD) Use of modified primer(s) or probe (partial substitution of sequences, e.g. degeneracy) Modified PCR reaction conditions using the same primers(s) and probe(s) Addition of an extra probe within the amplified region Change in probe chemistry (NAD)	
Major	Substitution of a recombinant antigen for a cell culture-derived antigen in an ELISA Change from an indirect to a competitive ELISA using a specific monoclonal antibody Change of primers and probes for different targets in different regions of the same or different gens (NAD)	Different species, e.g. cattle versus buffalo, domestic chicken versus wild birds Different specimen types, e.g. tracheal versus cloacal swabs, blood versus semen, different tissues or organs

ELISA = enzyme-linked immunosorbent assay; PCR = polymerase chain reaction; NAD = nucleic acid detection (tests);

When setting up a comparison experiment, the procedure should be guided by the purpose of the assay (Figure 1, step 1). For example, screening assays require high diagnostic sensitivity, and it is important to compare the limit of detection. In such a case a suitable dilution range and the number of replicates of a control sample have to be determined. A sufficient quantity of well characterised control sample material needs to be produced, aliquoted and stored appropriately.

If the objective is to assess and compare repeatability it is necessary to run well characterised replicates of control samples of different analyte concentrations spanning the expected operating range of the assay, e.g. a high, medium and low analyte concentration. For practical purposes, the example given in this chapter only uses a weak-positive control sample. It is good practice to visually inspect correlation of results between both methods. For example, a scatter diagram and a histogram are easily performed and provide immediate information about the type of correlation and distribution of data (Figures 2 and 3). Basic statistics help to set upper and lower limits and evaluate results, for example for limit of detection or repeatability (Tables 2 and 3). A more sophisticated approach to comparing and analysing results from a comparison study is a Bland–Altman plot (Figure 4 and Table 4).

Figure 5 is an example of how to increase the efficiency of comparison experiments by assessing different parameters simultaneously on a single plate, e.g. assessing analytical sensitivity using dilution steps of a target analyte in triplicate, followed by assessing analytical specificity using a number of negative samples (which do not carry the target analyte), and finally assessing analytical sensitivity using a number of samples from infected animals with different analyte concentrations. The use of replicates in the same run and between runs allows estimation of repeatability (Figure 5 and 6).

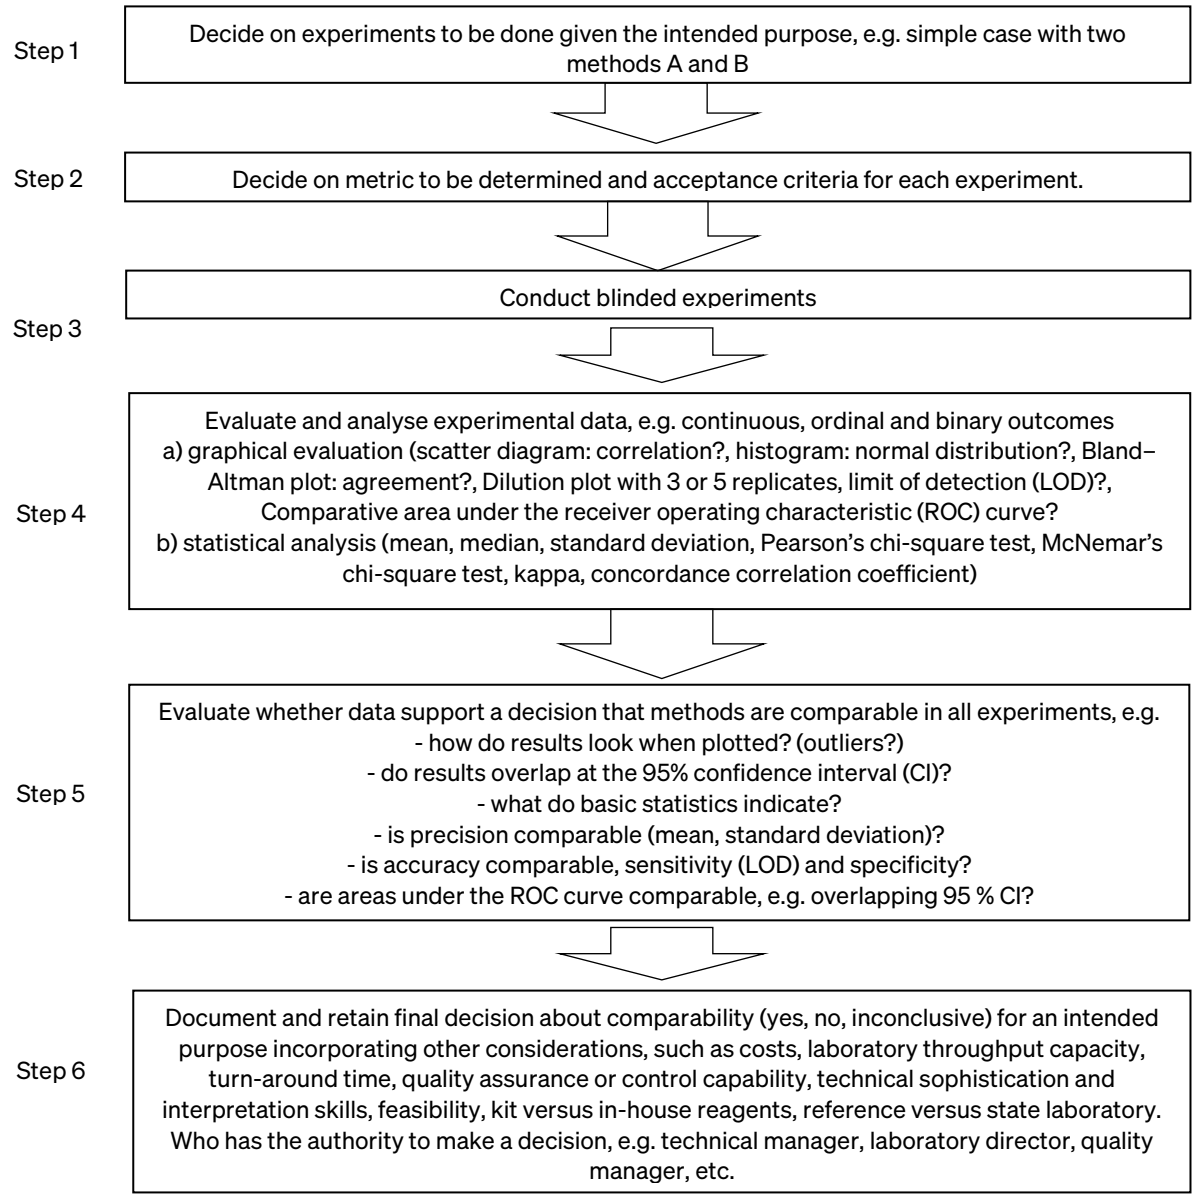
It is important to agree on acceptance criteria to evaluate the outcome of the experiment (Figure 1, step 2), e.g. confidence intervals can be asymmetric to allow for better performance of a novel assay. In this chapter a conservative 95% confidence estimate is regarded as acceptable for a limit of detection experiment (Figures 6 and 7). For comparison of repeatability, the mean and standard deviation (SD) or direct test results plus and minus

a given range can be used as acceptance criteria (Tables 3 and 4 and Figure 4). Results from a panel of infected and non-infected individuals provide information about comparative diagnostic sensitivity and specificity (Figure 8 and Tables 5 and 6).

Data used in Figures 2, 3 and 4 and Tables 2, 3 and 4 were produced using results from a repeatedly tested weak positive control sample in two TaqMan assays that target the M (M1 assay) and N (N1 assay) genes of Hendra virus.

Data for LOD experiments and plate layout in Figure 5, 6 and 7 are fictive. Data for ROC curves in Figure 8 and Tables 5 and 6 are taken from comparison experiments of different Influenza ELISAs in pigs.

Fig. 1. Factors to be considered for comparability studies of diagnostic tests.

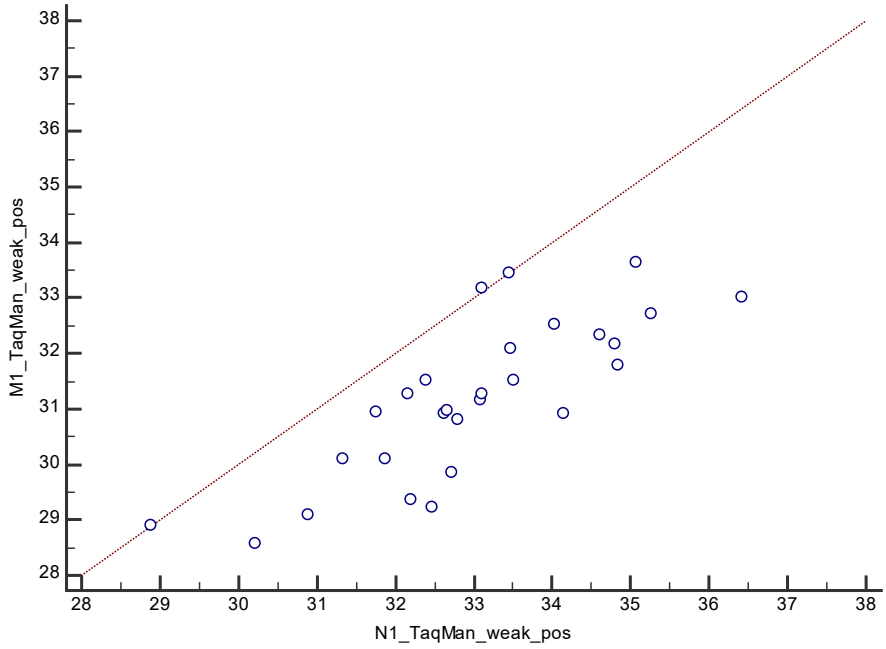


This chapter provides an overview of different approaches to the design of experiments and interpretation of results from assay comparison studies, e.g. analytical (limit of detection) and diagnostic sensitivity, analytical and diagnostic specificity, and repeatability. There are many fundamentally different tests but the examples provided stem from or refer to experiments with nucleic acid detection (NAD) and enzyme-linked immunosorbent assays (ELISAs). It can be assumed that the principles provided in this chapter are equally applicable to other tests.

B. VISUAL INSPECTION

A **Scatter diagram** is useful for visually evaluating the correlation between both methods initially, e.g. is the relationship linear or logarithmic? Are there outliers or missing values or artefacts? The example in Figure 2 uses results from a repeatedly tested weak positive control sample from two TaqMan assays that target the M (M1 assay) and N (N1 assay) genes of Hendra virus. Results show that data for the N1 assay are shifted to the lower right compared with the M1 assay, which indicates consistently higher values for N1 than for M1 assay. However the scatter diagram does not provide information about the agreement of the two tests. There is one exception to this rule, if all results for both tests would fall along the 45% diagonal line, the agreement would be 100%. In Figure 2 only three results fall along the diagonal line. In this paper we define agreement as a set of values of a candidate test that fall within the 95% CI of the results of the established test after repeated runs of the same well characterised control sample. Correlation measures the strength of the relation between measurements from these tests and is expressed as p value.

Fig. 2. Scatter diagram of a weak positive control sample after being tested 28 times in two different Hendra TaqMan assays, M1 and N1 (results expressed as cycle threshold [Ct] values).



Further analysis of results is given in Table 2 below, where r (correlation coefficient) = 0.8 and indicates a strong, positive correlation between the two methods. $p < 0.0001$ indicates that the probability that this association is due to chance is very low and the 95%CI (confidence interval) indicates that when these methods are used on a similar subject and under similar conditions, we are 95% confident that the true unknown value of r lies between 0.61 and 0.9.

Table 2. Statistical analysis of a weak positive control sample after being tested 28 times in two Hendra TaqMan assays, M1 and N1

Variable Y	M1 TaqMan weak positive
Variable X	N1 TaqMan weak positive
Sample size	28
Correlation coefficient r	0.8015
Significance level	$p<0.0001$
95% confidence interval for r	0.6112 to 0.9042

A **histogram**, where skewing to the left or to the right or other relevant characteristics such as a bimodal distribution would be detected is shown Figure 3.

Fig. 3. Histogram of a weak positive control sample after being tested 28 times in two Hendra TaqMan assays, M1 and N1 (results expressed as cycle threshold [Ct] values).

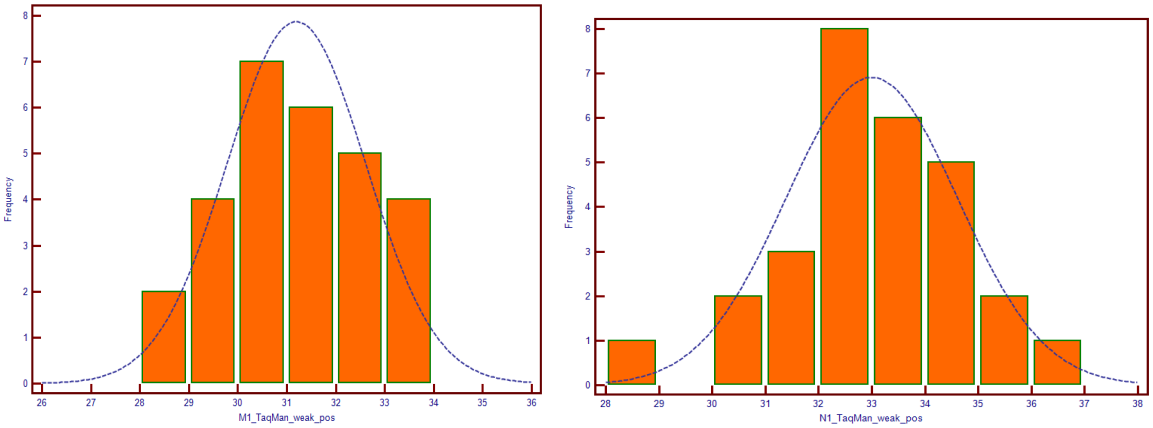


Table 3. Statistical analysis of a weak positive control sample after being tested 28 times in two Hendra TaqMan assays, M1 and N1 (results expressed as cycle threshold [Ct] values)

	M1 Taqman weak positive	**N1 Taqman weak positive**
Sample size	28	28
Lowest value	28.58	28.88
Highest value	33.63	36.42
Mean	31.19	33.00
Median	31.22	32.94
Standard deviation (SD)	1.42	1.62

C. REPEATABILITY

Assay variation can be assessed using replicates of an internal control sample when used in sequential runs over time. In this example, repeatability was compared for two different Hendra TaqMan assays targeting the N and M genes using a weak-positive internal control sample after 28 runs by the same operator on 14 days and during an 18-day period. Cycle threshold (Ct) results were summarised as the mean and standard deviation (SD) in Table 3.

Because the estimates are based on a single control sample, no formal comparison is necessary. Rather, if the predefined acceptance criteria for both assays were, e.g. 2 to 3 SDs or ± 2 to 3 Ct values then both assays would be considered comparable.

D. BLAND–ALTMAN PLOT

A very efficient way to simultaneously display and analyse results from a comparison study where 2 different measurements are made on the each sample (so called matched-pairs design) is a Tukey mean difference plot (Bland & Altman, 1999, 2007; Kozk & Wnuk, 2014). The plot is useful for revealing a relationship between the differences and the averages, evaluating any systematic biases and identifying possible outliers. Average Ct values obtained with methods A (M1 TaqMan assay) and B (N1 TaqMan assay) across a range of results are plotted along the x-axis and differences in the mean values, e.g. A minus B, are displayed on the y-axis (Figure 4, Table 4). In the example, the M1 TaqMan is compared with N1 TaqMan using results from a weak positive control sample after 28 runs. All differences are negative because the mean values for N1 TaqMan (Ct 33) are higher than M1

TaqMan (31.99) (Table 3). Subtracting N1 from M1 reveals that almost all values are negative, which indicates a systematic bias, e.g. the average difference between N1 and M1 was –1.81 (bias). Horizontal lines are drawn at the mean difference (–1.81), and at the limits of agreement, which are defined as the mean difference plus and minus 1.96 times the standard deviation of the differences, which, expressed in average Ct differences, are 0.1 to –3.71. Results in Table 4 show that the 95% CI for the mean difference (–2.18 to –1.43) exclude zero and hence, it cannot be concluded that the two methods are comparable. Adjustment of the cut-off could help to counterbalance this apparent systematic bias between both methods after corroborating these findings with larger sample numbers and over the range of expected results.

One measurement is made by each method on each sample (matched-pairs design) to compare repeatability between the two methods over the measurement range, e.g. for competitive antibody ELISAs it is known that variation increases with the decrease of the analyte concentration in the sample. A negative or weak-positive control sample may have significantly higher variation than high-positive control samples. Figure 4 shows three results that lie along the line for the 0 value, e.g. the line where results for both tests are identical because the difference is zero. These are the same results that fall on the diagonal line of equality in the scatter diagram in Figure 2 at values of 28.9, 33.10 and 33.45 for both assays.

Fig. 4. Bland–Altman plot showing differences of cycle threshold (Ct) values in two Hendra TaqMan assays, M1 and N1 for a weak-positive control sample after being tested 28 times.

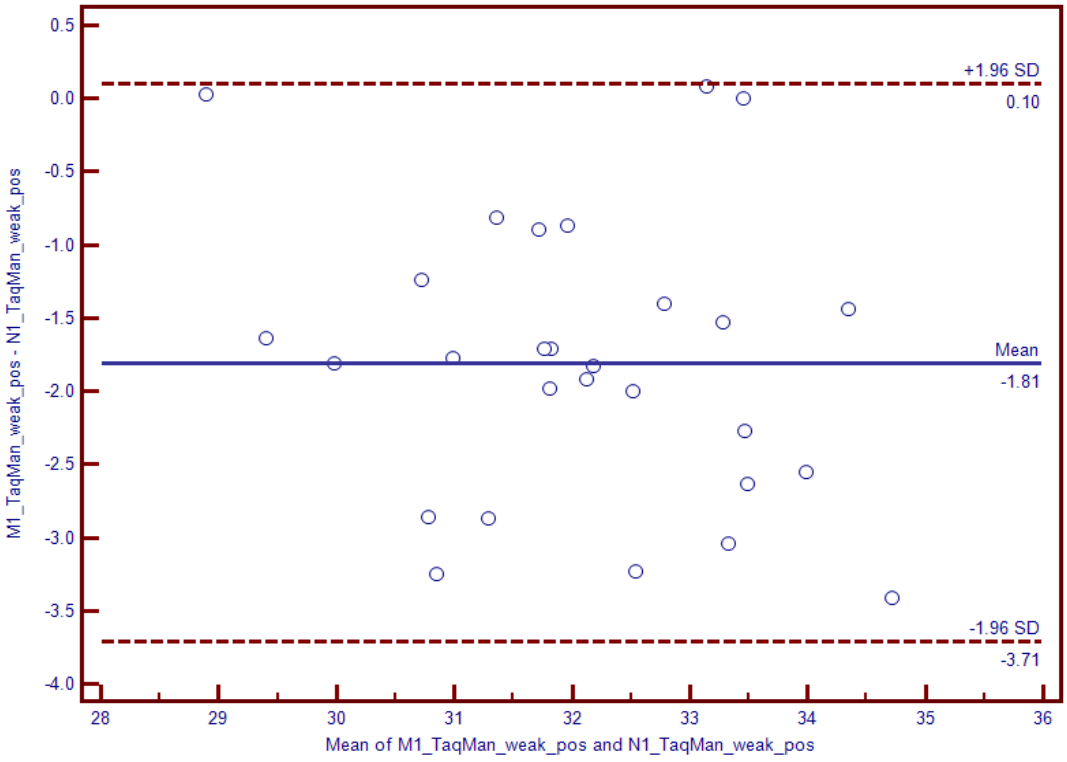

Table 4. Statistical analysis for Bland–Altman plot

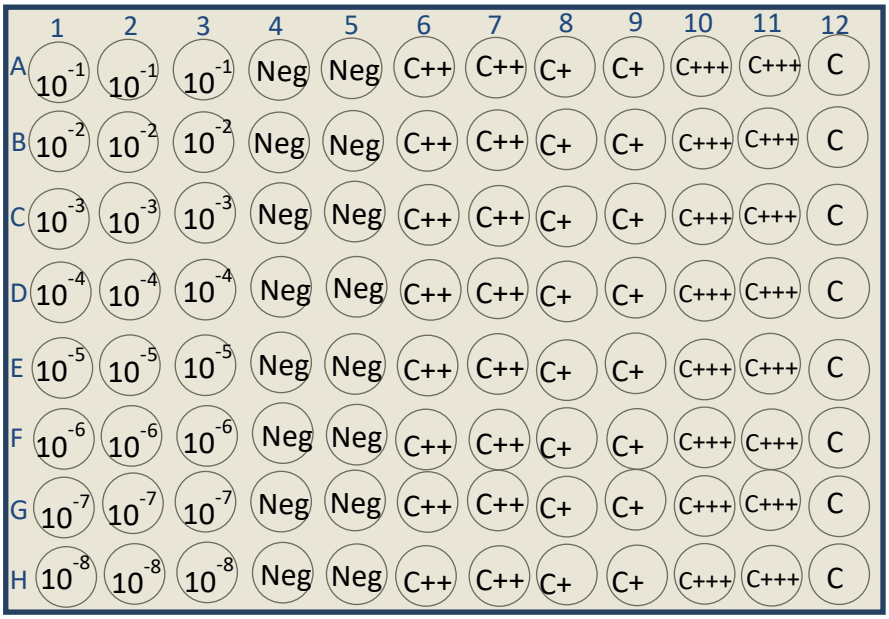
Method A	M1 TaqMan weak positive
Method B	N1 TaqMan weak positive
Differences	
Sample size	28
Arithmetic mean	–1.8054
95% CI	–2.1831 to –1.4276
Standard deviation	0.9741

E. LIMIT OF DETECTION (LOD) EXPERIMENT

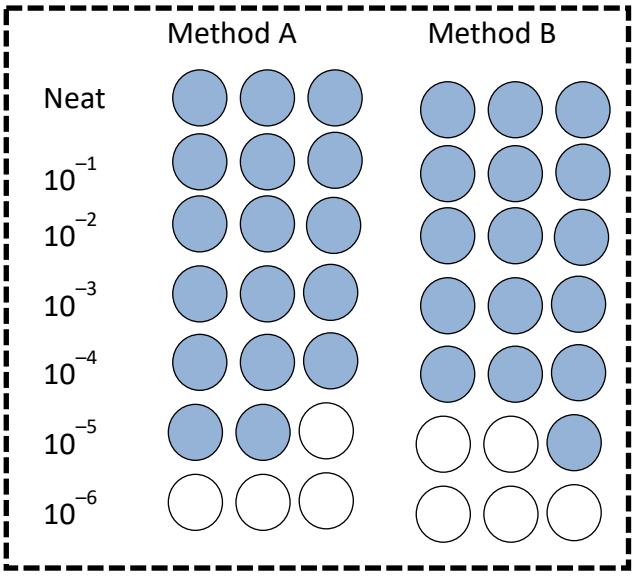
An example of a plate layout for a comparability study of a molecular test is given in Figure 5. Limit of detection (three replicates of positive samples in a dilution series from 10^{-1} to 10^{-8} [analytical sensitivity]), diagnostic specificity (negative diagnostic samples from non-infected animals or animals that have been infected with a non-target pathogen [Neg] tested in duplicate), diagnostic sensitivity (samples from field infected animals of different activity, e.g. extremely high positive [C+++], very high positive [C++], high positive [C+] and positive [C] tested in duplicate), and repeatability are assessed. Cross-contamination can be also evaluated as strong positive samples are placed next to negative samples.

Fig. 5. Layout of 96-well plate to assess analytical Se, diagnostic Se and Sp and repeatability.



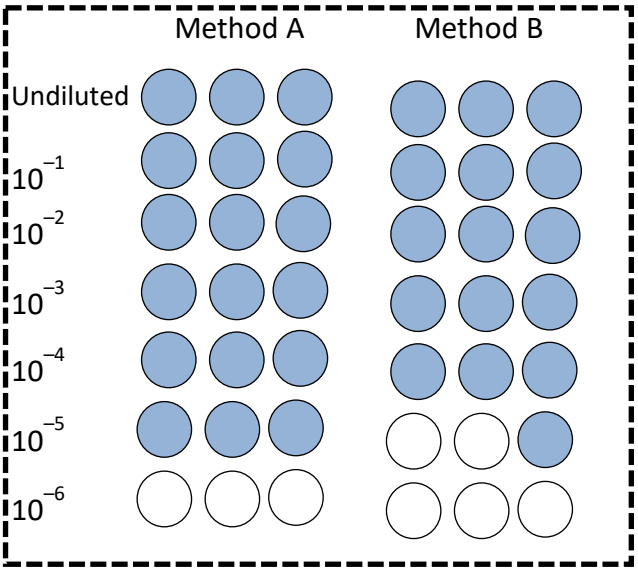
The limit of detection (LOD) is a measure of the analytical sensitivity (ASe) of an assay. The LOD is the estimated amount of analyte in a specified matrix that would produce a positive result at least a specified per cent of the time. Figures 6 and 7 represent hypothetical results of a LOD experiment. For example, in a titration using tenfold dilutions all replicates at all dilutions might show either 100% or 0% response. There are two choices at that point. The last dilution showing 100% response may be accepted as a conservative estimate of the lower limit of detection. A more accurate estimate may be obtained by a second stage experiment using narrower intervals in the dilution scheme focusing on the region between 100% and 0%. The first step is to produce, aliquot and blind a sufficient number of samples to carry out the experiment. The second step is to produce a set of analyte dilutions, preferably using sample matrix as diluent, rather than buffer, which reflect the measurement range of the method, e.g. in a tenfold dilution series, 10^{-1}, 10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}. Practical examples often use 3–5 replicates per dilution step. Using a conservative estimate of 100% (all 3 wells at the highest dilution dark = positive) Figures 6 and 7 show comparable and non-comparable outcomes, respectively. Method A represents the validated and method B the new method.

Fig. 6. Example of a limit of detection (LOD) experiment with an acceptable outcome.



In Figure 6 at the 10^{-4} dilution all replicates from method A and method B are positive (blue). At the 10^{-5} dilution only two out of three wells are positive for method A and one out of three is positive for method B. As the limit of detection is defined as the dilution where all wells must be positive results from the 10^{-5} dilution downwards are not considered for comparability. Applying these criteria the limit of detection in Figure 6 is the same for methods A and B and therefore the two methods can be regarded as comparable.

Fig. 7. Example of a limit of detection (LOD) experiment with a non-acceptable outcome.



In Figure 7 the highest dilution of all three replicates is at 10^{-5} for method A. In contrast the highest dilution where all three replicates are still positive for method B is at 10^{-4}. Consequently, the limits of detection of methods A and B cannot be considered comparable if a single log dilution is not acceptable. It is advisable to repeat the experiment several times before making a final decision on comparability.

F. COMPARISON OF ROC CURVES

Receiver operating characteristic (ROC) analysis is a powerful method to assess and compare the overall accuracy of a diagnostic test, e.g. diagnostic sensitivity (DSe) and diagnostic specificity (DSp) at different cut-offs of one or more different or modified tests (Greiner *et al.,* 2000). The central measurement is the area under the curve (AUC), e.g. a value of 1 indicates a test with 100% DSe and 100% DSp. In this case there is perfect separation

of the values of the two groups, i.e. there is no overlapping of the distributions and the ROC curve will reach the upper left corner of the plot. In contrast a value of 0.5 indicates no discrimination between infected and non-infected individuals beyond chance; the ROC curve coincides with the diagonal indicating that the test is useless. Values between 0.5 and ≤0.7 can be considered less accurate, from 0.7 to ≤0.9 moderately accurate and from 0.9 to <1 as highly accurate (Greiner *et al.,* 2000).

Figure 8 shows results from four antibody ELISAs for influenza virus in pigs. The serum panel consisted of 168 positive and 77 negative sera using the haemaglutination inhibition as a reference test (*n*=245). When compared on these diagnostic samples the following ranking was established: test 1 (AUC = 0.988), test 4 (AUC = 0.988), test 3 (AUC = 0.929) and test 2 (AUC = 0.814) (Table 5). For this matched pair design experiment the 95% CI for the differences of the Area Under the ROC curve (AUC) can be used as an indicator for statistical significance (Table 6). In summary, the test with the best DSe and DSp and the highest area under the curve (0.988) is test 1. The result of 0.988 means that a randomly selected individual from the positive group has a test value larger than that for a randomly chosen individual from the negative group 99% of the time (Zweig & Campbell, 1993).

Another way to compare results is to evaluate AUC differences. For example for test 1 and 2 the difference between the AUC was 0.0173, for test 1 and test 3 the result was 0.058, for test 1 and 4 the result was 0.00019, for test 2 and 3 the result was 0.1150, for test 2 and 4 the result was 0.174 and for test 3 and 4 the result was 0.0586 (Table 6). The tests with the highest AUCs and smallest difference of AUCs were test 1 and test 4, e.g. both tests had an AUC of 0.988, overlapping 95% CI, the difference between the AUCs was as low as 0.00019 and a *p* value of 0.98 indicated no statistically significant difference at the 5% significance level. Lower AUC values, lack of overlapping 95%CI, significantly increased AUCs and *p* values <0.05 indicated lack of agreement of other test combinations, e.g. 1 vs 3, 1 vs 2, 2 vs 3, 2 vs 4 and 3 vs 4. Test 1 0.964 to 0.997, test 2 0.760 to 0.861, test 3 0.889 to 0.958, test 4 0.965 to 0.997.

More complex comparison studies with tests based on similar diagnostic and biological principles using frequentist and classical statistical approaches have been published (Brocchi *et al.,* 2006; Engel *et al.,* 2008). See also Chapter 2.2.5. *Statistical approaches to validation*.

Fig. 8. Comparison of receiver operating characteristic (ROC) area under the curve (AUC) for four different ELISAs to detect antibodies against influenza virus in pigs.

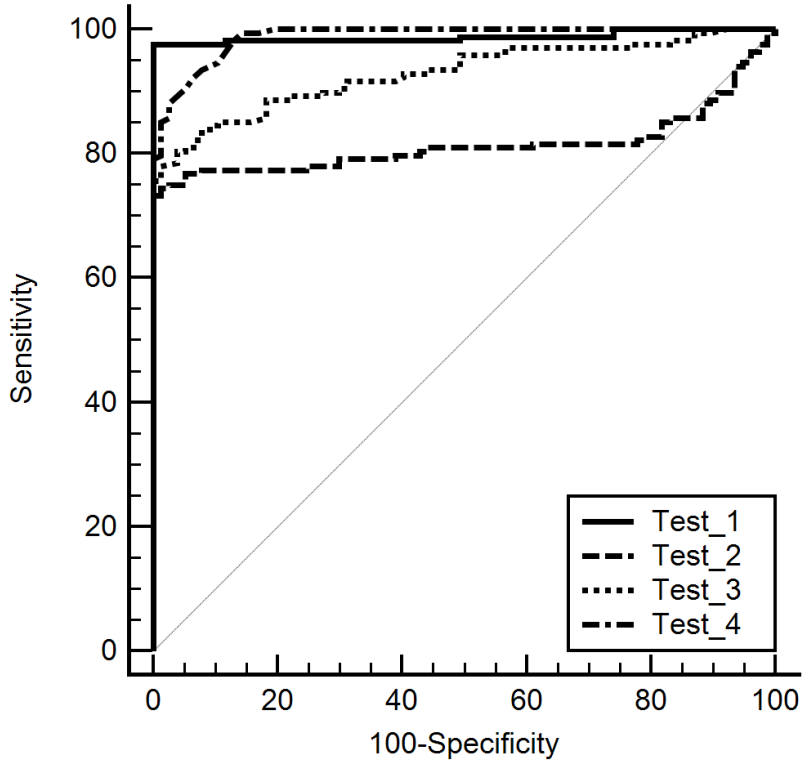


Table 5. Receiver operating characteristic (ROC) comparison of area under the curve (AUC) and p-values for four different ELISAs to detect antibodies against influenza in pigs

Parameter	Test 1	Test 2	Test 3	Test 4
Area under ROC curve	0.988	0.814	0.929	0.988

Table 6. Pairwise comparison of ROC curves

	Test 1 vs 4	Test 1 vs 3	Test 3 vs 4	Test 2 vs 3	Test 1 vs 2	Tetst 2 vs 4
Difference between AUC	0.0002	0.055	0.0589	0.115	0.173	0.174
95% CI	–0.016 to 0.016	0.025 to 0.092	0.027 to 0.090	0.069 to 0.161	0.117 to 0.230	0.118 to 0.229
Significance level	p=0.9808	p =0.0007	p =0.0003	p <0.0001	p <0.0001	p <0.0001

G. DISCUSSION AND CONCLUSIONS

Results from comparison experiments must be evaluated to reach a conclusion as to whether both methods are comparable using statistical analyses and objective assessments to assist with a final decision (NATA, 2013). However, often other criteria such as costs/equipment, throughput capacity, turn-around time, quality assurance capability, technical sophistication, acceptance in regulatory or scientific community and interpretative skills also need to be considered in decision-making (Figure 1, Step 6). It is important to have a process in place, which clarifies who has the authority to make the final decision whether methods are comparable, e.g. technical manager, laboratory director, quality manager.

For example, comparison of two TaqMan assays indicated strong and positive correlation. Repeatability of both methods was comparable when applying 2–3 SD or ± 2–3 Ct. Ct values from a weak positive-control sample were consistently lower for the M1 than for the N1 TaqMan, indicating a slightly superior Se of the M1 assay. If used as a screening test the M1 would be more suitable due to its higher Se. Results were corroborated by testing diagnostic samples from Hendra virus outbreaks between 2011 and 2013 (data not shown). On the other hand having two tests, which target different genes increases the chance of not missing a new variant. In the case of a deadly zoonosis such as Hendra virus this is an important consideration.

Results from the Bland–Altman Plot in Figure 4 and Table 4 show that statistical results sometimes are difficult to interpret, e.g. the 95% CI for the mean difference excludes zero. This might be interpreted as a lack of comparability but change in the cut-off value can be used to compensate for this outcome.

ROC analysis of 4 different swine influenza ELISAs (Figure 8 and Tables 5 and 6) indicated two tests of almost identical DSe and DSp (Tests 1 and 4). At the same time it helps to rank the performance of the other tests. Under these circumstances cost, availability and other criteria will determine the final decision as to which test is the most suitable for a designated purpose.

On the other hand, not all parameters need to be addressed in every method comparison study. For example, an assessment of cross-contamination would be necessary for changes in equipment such as manual vs robotic nucleic acid extraction procedure but not for changing a key reagent, e.g. a different primer or probe. It is good practice to decide on relevant parameters and acceptance/rejection criteria before the experiment. The most relevant question is whether the new test is fit-for-purpose.

It is in the nature of veterinary diagnostic testing to allow for flexibility when it comes to the specification of acceptance limits, e.g. when comparing two different molecular tests it could be that the difference is no more than 1, 2 or 3 Ct in 95% (99%) of tested samples, no more than 10% of the average of the 2 samples in at least 95% (99%) of tested samples, no more than 1, 2, or 3 SD of the samples. It is recommended to consider relevant parameters and limits up front although the qualitative considerations (e.g. cost, ease of testing, rapidity of

results) probably come in at the end. Whatever parameter is chosen as a basic rule the candidate test should on average not be significantly underperforming the validated test.

The data generated and the decision making process for the acceptability of the change should be clearly documented and retained to show an audit trail.

H. DATA ANALYSIS

Data were stored and grouped in Microsoft Excel. Analysis and plotting for scatter diagrams, histograms, data distribution and plotting, Bland Altman Plots, comparison graphs and ROC analysis were performed using MedCalc (MedCalc®, Version 12.4.0.0, 64 bit, Window XP/Vista 7/8, *www.medcalc.org*, Copyright 1993–2013, MedCalc software bvba).

CHAPTER 2.3.1.

THE APPLICATION OF BIOTECHNOLOGY TO THE DEVELOPMENT OF VETERINARY VACCINES

INTRODUCTION

The practice of vaccination for the prevention of animal disease has been used for centuries and has proven to be a powerful tool for the alleviation of animal suffering as well as the economic well being of producers of animal products. Up until 15–20 years ago, vaccines had changed little from those originally pioneered by Jenner and Pasteur. Since that time there have been significant changes in the types of vaccines available owing to a number of factors, including compatibility with eradication programmes and international trade policies as well as cost-effectiveness of production. The first recombinant vaccines were introduced in the late 1980s to control Aujeszky's disease and rabies in wild-life (Pastoret et al., 1988) and are the forerunners of similar products that will be available in the future.

The approaches used in the development of vaccines have expanded rapidly as the result of increased knowledge of the mechanisms by which protective immunity is induced, and the explosion of genomic data on both pathogens and their hosts. The associated evolution of new technology in the field of molecular biology and immunology has furthermore had a large impact on the development of new vaccine strategies and the quality of the products that are produced. It has enabled the design of vaccines targeted for the control and eradication of specific pathogens within the framework of regional, national and international requirements. Use of recombinant technologies bring with it the need for the application of a risk–benefit assessment that takes into account the specific aspects that need to be considered, particularly with respect to safety (see Appendix 1.1.8.1 Risk analysis for biologicals for veterinary use*, to Chapter 1.1.8* Principles of veterinary vaccine production *of this* Terrestrial Manual*).*

This chapter describes a range of technologies that are used to produce vaccines engineered for a specific purpose. The categorisation is aimed to assist the reader to understand the technologies employed, but it should be recognised that the categories are not mutually exclusive (i.e. reverse genetics may be used to produce a chimeric vaccine). In principle, the technologies can be used to change the target pathogen itself to alter its properties by deletion, insertion, other genetic modifications, or they can be used to modify the isolated genes or coding sequences of pathogens to produce specific immunogens associated with protective immunity.

A. REVERSE GENETICS

The development of a reverse genetics system for a range of different RNA and DNA viruses has revolutionised the field of virology by making it possible to introduce designed mutations, insertions and deletions into the viral genome of live viruses. It has by now been used in a range of applications that include the attenuation of viruses, the modification of host specificity and the generation of replication-deficient viruses. These strategies have also been applied to the development of new vaccine strategies and are widely used in the characterisation of the structure and function of individual viral genes and coding sequences.

The technology of reverse genetics involves the generation of a cloned copy of complementary DNA (cDNA) from RNA by reverse transcription *in vitro*, manipulating DNA *in vitro* followed by generating the modified live virus by transfection of permissive cells with the cloned DNA(s).The technology was first demonstrated using the bacteriophage Q-Beta, a positive-strand RNA virus (Taniguchi, 1978). Subsequently, a large number of positive-strand RNA viruses including severe acute respiratory syndrome (SARS) coronavirus, with large genomes have

been rescued, which has helped in the study of the biology of these viruses and the development of new live attenuated viral vaccines. For example, reverse genetics was used to develop an infectious clone of transmissible gastroenteritis virus (TGEV), which induced lactogenic immunity in immunised pigs (Sola *et al.,* 2003). This novel technique has also been used to develop a modified porcine respiratory and reproductive syndrome virus, which can be used as a DIVA (differentiating infected and vaccinated animals) vaccine to help differentiate between vaccinated and infected pigs (de Lima *et al*., 2008).

Owing to the inherent characteristics of negative-strand RNA viruses, it took years of work before this technique could be developed and used for generating engineered viruses containing negative-strand RNA genomes. Reverse genetics was first developed for influenza virus, a segmented negative-strand RNA virus. Since then, this technique has been successfully used for the generation of a number of RNA viruses containing either unsegmented or segmented negative-strand genomes. For example, the use of this technique has led to the development of a vaccine for avian influenza virus in which the engineered virus contained a haemagglutinin (HA) gene from an H5N1 virus and a neuraminidase (NA) gene from a H2N3 virus, using a H1N1 backbone (Meeusen *et al*., 2007). The resultant inactivated H5N3 virus vaccine induced complete protection in birds against highly pathogenic H5N1 challenge. A reverse genetics strategy has also been used in the development of Foot and mouth disease, Classical swine fever, and Newcastle disease vaccines (see chapters 3.1.8, 3.8.3 and 3.3.14, respectively). More recently, reverse genetics systems have been developed for segmented double-stranded RNA viruses including bluetongue virus (BTV) introducing the possibility of new vaccine development strategies for these viruses (Boyce *et al*., 2008).

Disabled infectious single-cycle (DISC) vaccine involve the deletion of an open reading frame coding for a key protein involved in the viral replication or viral capsid formation (Widman *et al*., 2008). The DISC virus is isolated in cells expressing the key protein, thus providing the missing protein in *trans*. Such virus, when injected in animals, can complete only one round of replication without producing a progeny virus. Vaccines based on DISC viruses are more stimulatory than a killed virus vaccine and are devoid of problems associated with live vaccines.

B. RECOMBINANT VECTOR TECHNOLOGY

Advances in reverse genetics, genomics, and proteomics have facilitated the identification of mechanisms of virulence, host-pathogen interactions, and protective antigens from many pathogenic microorganisms and also the development of suitable vehicles/vectors for delivery of these antigens to the host. The availability of bacterial and viral genome sequences has facilitated the rapid construction of defined deletions in the genomes of a wide variety of pathogens, which not only results in attenuation, but also creates space for the insertion of foreign genes coding for antigens from heterologous microbes. In general, live bacterial or viral vectors share several characteristics including ease and economy of production, non-integration into the host genome, stability and a reasonable capacity to insert genes coding for heterologous antigens. In addition, as with any live vaccine, the vector should be avirulent and the impact of immunity to the vector should be evaluated.

1. Bacterial vectors

In general bacterial vectors are attenuated by deletion of genes required for key metabolic processes or genes associated for virulence. Although they are not used routinely in animals, rapid progress is being made in developing and evaluating different bacteria as vectors. For several years, BCG (Bacillus Calmette–Guerin) and *Salmonella* have been developed as vectors for delivering vaccine antigens to animals and the latter has been used for the generation of live vaccine strains for poultry. There are currently a number of other bacterial vectors being developed based on commensal microorganisms (*Lactococcus, Streptococcus, Lactobacillus* and *Staphylococcus*) or attenuated pathogenic organisms (*Shigella, Bacillus, Yersinia, Vibrio, Cornebacteria,* and *Bordetella*), all of which are being evaluated for their ability to induce protective immunity.

2. Viral vectors

Most viral vectors are developed using viruses that are associated with mild or no disease or using viruses that are pathogenic but attenuated by deletion of virulence genes. Replication competent virus vectors, which can produce progeny virus, as well as replication-defective virus vectors, which do not produce progeny virus, have been developed and evaluated as vaccine delivery vehicles. A number of commercial vaccines based on DNA virus vectors, including poxviruses and herpesviruses, have been successfully licensed for use in veterinary medicine (reviewed in Gerdts *et al*., 2006). These include vectors based on vaccinia virus, canarypox virus, fowlpox

virus and turkey herpesvirus. A number of viral vectors have been developed or are in the process of being developed, improved and evaluated. These include RNA viruses such as Venezuelan equine encephalitis virus, Newcastle disease virus and feline foamy virus as well as DNA viruses such as adenoviruses, herpesviruses and pox viruses, Fowl pox and canary pox vectors have been used in a wide range of applications (MacLachlan *et al.,* 2007; Swayne, 2009) whereas replication-deficient human adenovirus vectors have been used very successfully in the development of FMDV vaccines (Rodriguez & Grubman, 2009). Licensed canary pox vaccines include vaccines against equine influenza and feline leukaemia. Other licensed vector vaccines include the herpesvirus of turkeys vectored with an infectious bursal disease insert.

C. GENE-DELETED VACCINES

The knowledge of specific virulence factor(s) of a pathogen and the availability of recombinant DNA technology has facilitated the creation of specific gene-deleted pathogens for use as live vaccines. The approach of creating and testing defined gene deletions ultimately aids in reducing the pathogenicity/virulence of the organism without affecting the immunogenicity. Such gene-deleted organisms can be used as vaccines as they retain the immunogenic features of the wild-type organism but cannot cause disease. However, to be effective as viable vaccine(s), these organisms should be genetically stable, easy to grow and easy to administer. So far, genes involved either in determining virulence or regulating key metabolic pathways of the organism(s) have been targeted for such deletions.

This approach has been successfully used to create several live attenuated vaccine strains of bacterial pathogens that are genetically stable, safe to use and induce better protection than killed vaccines. Gene-deleted *Salmonella enterica* serovar *typhimurium* and serovar *enteritidis* vaccines have been licensed for use in poultry (Babu *et al*., 2004; Meesun *et al*., 2007) and similarly, an *aroA* gene-deleted *Streptococcus equi* vaccine has been licensed for use in horses (Jakobs *et al*., 2000; Meesun *et al*., 2007).

This technology has also been successfully used to create live attenuated vaccine strains of viral pathogens that are genetically stable and can be used as marker vaccines to differentiate between vaccinated and infected animals. A double gene (gE and TK) deleted pseudorabies virus marker vaccine has been licensed for use in pigs (Ferrari *et al*., 2000; Meesun *et al*., 2007) and similarly, gE deleted a bovine herpesvirus-1 marker vaccine has been licensed for use in cattle (Meesun *et al*., 2007; Van Oirschot *et al*., 1996).

D. CHIMERIC VIRUSES

Chimeric viruses are defined as recombinant viruses that may contain parts of two closely related viral genomes. For example, a chimeric virus could be one that contains structural genes of one viral serotype and nonstructural genes of another serotype of the same virus. Alternatively, a chimeric virus would be one that contains part of the genome from different members belonging to the same virus family. In principle, chimeric viruses display the biological characteristics of both the parent viruses. One of the main advantages of this approach is that a single dose of chimeric virus delivers the complete repertoire of antigens closely resembling the pathogen(s), which can induce protective immune response against multiple viral pathogens belonging to or different serotypes of the same viral pathogen.

The availability of infectious full-length complementary DNA (cDNA) clones of different RNA viruses using reverse genetics technologies has led to novel vaccine development strategies. Chimeric pestiviruses have been constructed using an infectious cDNA clone containing the classical swine fever virus (CSFV) genome or the bovine viral diarrhoea virus (BVDV) genome backbones. In one instance, a chimeric pestivirus was constructed by replacing the BVDV E2 coding sequence in the infectious DNA copy of BVDV strain CP7 with the corresponding E2 coding sequence of CSFV strain Alfort 187 (Reimann *et al.,* 2004). Another chimeric virus was constructed by replacing the CSFV E2 coding sequence in the infectious DNA copy of CSFV vaccine strain C with the corresponding E2 coding sequence from BVDV (van Gennip *et al.,* 2000). These chimeric viruses appeared to be attenuated in pigs, induced complete protection against CSFV challenge and helped to discriminate between vaccinated and infected pigs (Reimann *et al.,* 2004; van Gennip *et al.,* 2000).

In another application, chimeric porcine circoviruses (PCVs) have been isolated using infectious cDNA clones of porcine circovirus PCV1 in which the capsid protein from pathogenic PCV2 was used to replace the corresponding gene in the nonpathogenic PCV1 strain (PCV1-2). Likewise, the capsid gene in PCV2 has been replaced with the

gene from PCV1 (PCV2-1). The chimeric PCV1-2 virus appeared to be attenuated in pigs and induced protective immunity against wildtype PCV2 challenge in pigs (Fenaux *et al.,* 2004).

This platform technology has also been used to generate chimeric flaviviruses. In one example, a chimeric virus was generated by replacing the coding sequences for structural proteins of yellow fever YF-17D virus with those of West Nile virus (WNV). A single dose of this chimeric flavivirus vaccine induced both cell-mediated and humoral immune responses in horses, and provided protection against WNV challenge without causing any clinical illness (Meeusen *et al*., 2007). The same platform technology has also been used to develop human vaccines for Japanese encephalitis virus, WNV and Dengue virus. Although chimeric flavivirus vaccines have shown satisfactory safety profiles and protective efficacies, caution should be used in evaluating chimeric viruses for the change in virulence.

E. SUBUNIT VACCINES

Subunit vaccines composed of semi-pure or purified proteins have been commercially available since the early 1980s, with subunit components produced by recombinant DNA technology available since the 1990s (Cohen, 1993; Rhodes *et al.,* 1994; Ulmer *et al*., 1993; 1995). The latter have attracted growing interest and activity since that time. Subunit vaccines do not include live recombinant vector technologies, which provide the delivery of recombinant proteins *in vivo.* The field of genomics and related areas has revolutionised the manner in which microbial antigens are identified. Since the first bacterial genome was sequenced in 1995, there has been a huge increase in the number of bacterial, viral, and parasite genomes for which genome sequences are available. Indeed, virtually all pathogens of animals are represented and those pathogens that are not can readily be obtained in less than a day. More importantly, the development of the bioinformatics resources and tools that are required to analyse these genomes has proceeded in parallel and it is now relatively easy to identify surface-exposed antigens, specific B- and T-cell epitopes, etc. There is no requirement to have the ability to grow the organism in culture: for example subunit vaccines for *Piscirickettsia salmonis,* a salmonid pathogen, have been developed even though the organism could not be readily grown (Kuzyk *et al.,* 2001).

The production of subunit antigens can be achieved by both conventional biochemical or recombinant DNA technologies. The latter involves a range of prokaryotic and eukaryotic expression systems including yeast, insect cell and plants (Chichester & Yusibov, 2007) by means of a variety of integrated or transient expression strategies. Biochemical techniques remain useful in some cases where recombinant expression is not appropriate, such as antigens requiring complex assembly (e.g. fimbriae), or when post-translational modification is necessary. For example, *Campylobacter jejuni* is one bacterial species that glycosylates many surface proteins and, as such, they are best produced in *C. jejuni* rather than heterologous expression systems, although *Escherichia coli* strains have been engineered to carry out the same function (Wacker *et al.,* 2002). An excellent example of a subunit vaccine composed of an authentic antigen that retained three dimensional structure was the original *E. coli* K99 vaccine for calf scours, which was tested three decades ago (Acres *et al.,* 1979). This product was based on the K99 fimbrial antigen, which could readily be extracted from cells by heat treatment, thus retaining the three dimensional fimbrial structure. Another example includes a baculovirus expressed vaccine against porcine circovirus type 2 (Fachinger *et al.,* 2008). In a number of cases the expressed subunit vaccine protein spontaneously assembles into well defined particles that may resemble virus particles. These virus-like particles (VLPs) are a sub-class of subunit vaccines (Roy & Noad, 2008) and their application in vaccine development is reviewed in section F. Vaccines containing ORF 2 protein of PCV-2 expressed in baculovirus has been commercialised.

Subunit vaccines could have some advantages over live attenuated and inactivated vaccines, including the ability to induce strong humoral and cell-mediated immune response. The vaccines furthermore have an excellent safety profile, and can be used in combination with other subunit vaccines. However, efficacy is dependent on the protective immunity being induced by inoculation of a single or set of defined recombinant proteins. Experience has shown this may be affected by the gene expression system used. In addition, subunits vaccines may be expensive to produce for some glycoproteins and may require the use of adjuvants to enhance immune responses.

One of the biggest advantages of subunit vaccines is that they are generally compatible with DIVA strategies as long as the antigen is not being used as a marker. In the case of bovine herpesvirus, glycoprotein gD has been successfully used in subunit vaccine formulations. Although immunisation with gD has proven to be protective at an individual animal level (Harland *et al.,* 1992; van Drunen Littel-van den Hurk *et al*., 1994), it has not reduced the prevalence of the virus in the field, thus limiting its use. Subunit vaccines against a variety of other respiratory and

enteric viruses, including BVDV, BRSV, PI3, rotavirus, and coronavirus have been successfully tested, although none of these is used on a commercial basis. Bacterial subunits have arguably proven more successful than their viral counterparts. This is because of the cost-effectiveness of growth of both conventional and recombinant organisms and a general requirement for a Th_2-biased immune response in many cases. Recombinant vaccines are commercially available for respiratory pathogens such as *Mannheimia haemolytica* and *Actinobacillus pleuropneumoniae* based upon the leukotoxins produced by these organisms, as well as transferrin-binding proteins. *Actinobacillus pleuropneumoniae* is an excellent example of a vaccine composed of subunits selected on cross-serotype reactivity, thus providing broad-spectrum protection against disease. Likewise a vaccine against atrophic rhinitis containing a non-toxic derivative of *Pasteurella multocida* dermonecrotic toxin produced by a genetically modified *Escherichia coli* strain together with a conventional *B. bronchiseptica* bacterin has been commercialised.

Vaccines against CSF demonstrate well the need to target recombinant technology to a particular purpose. Conventional, live attenuated CSF vaccines have a rapid onset of immunity and are effective at preventing transmission of infection (Van Oirschot, 2003) but have the disadvantage that it is not possible to differentiate infected pigs from those that have merely been vaccinated. Commercial E_2 subunit vaccines have a slower onset of immunity and reduce but do not prevent viral shedding. However, they enable a DIVA strategy to be followed thereby facilitating a 'vaccination to live' strategy. Their use is therefore likely to be of particular benefit in high value breeder pigs where the vaccine can be used to limit the clinical impact of the disease whilst allowing individual infected pigs to be identified and eliminated.

F. VIRUS-LIKE PARTICLES

Virus-like particles (VLPs) are supra-molecular structures composed of one or more recombinant proteins. The particles form through self-assembly and typically range from 20 to 100 nm in size. Depending on the origin they can be icosahedral or rod-like in structure (reviewed in Jennings & Bachmann, 2008). VLPs offer the advantage of formulating the vaccine antigen in a particulate structure, thereby increasing the immunogenicity of the vaccine. VLPs can be used as either vaccine itself or as carrier for genetically fused (chimeric), incorporated or covalently linked antigens. VLPs have been extensively studied for the past 20 years, with human vaccines against hepatitis B virus (Zuckerman, 2006) and human papillomavirus (Stanley, 2008) commercially available and several vaccines for veterinary application in development. These include vaccine for bluetongue virus, rota- and parvovirus.

VLPs offer several advantages for the use as vaccine including a high safety profile, the similarity to viral and bacterial structures, the ability for large-scale production and the possibility of combining the VLPs with other adjuvants. Typically, immunisation with VLP induces rapid and strong antibody responses. Similar to viruses and bacteria multiple copies of the vaccine antigens are displayed in a highly repetitive and ordered, quasi crystalline-structure (Bachmann & Zinkernagel, 1996), which can cross-link the B cell receptor resulting in activation of the B cell and subsequent induction of T-independent IgM responses (Thyagarajan *et al*., 2003).). Furthermore, this enables interaction with the complement system resulting in increased phagocytosis. Moreover, the particulate structure of VLPs also enhances uptake by dendritic cells and subsequent cross-presentation of the antigen. It was demonstrated by Lenz *et al.* (2001) that cross-presentation of particulate antigens was more effective than presentations of soluble antigens. However, the induction of T cell responses overall is still not as effective as those induced by live vaccines. To overcome this, VLPs have been successfully combined with molecular adjuvants such as CpG ODN and single-stranded RNA. Other VLPs have been demonstrated to directly stimulate dendritic cells (DC.) For example, L1 protein-VLPs of papillomavirus have been shown to directly activate DC.

VLPs can either be used as vaccine itself or be used as carrier for recombinant antigens, either incorporated, directly, genetically fused or covalently linked. For example, the bovine rotavirus virus protein 6 (VP6) forms VLPs that are highly immunogenic and already confer protection against challenge infection (Redmond *et al.,* 1993). However, using the VP4 and VP7, other antigens can be covalently linked to the VP6 particles and used for immunisation (Redmond *et al.,* 1993). Other prominent examples include the hepatitis B surface antigen VLPs (HBsAg-VLP), human immunodeficiency virus 1, dengue virus VLPs, norovirus VLPs, and influenza A VLPs. Examples of VLPs used as carriers include the well characterised hepatitis B core antigen VLPs (HBcAg VLPs; [Blanchet & Sureau, 2006; Pumpens & Grens, 2001]) as carrier for the influenza a M2 protein (M2-HBcAg [Jegerlehner *et al.,* 2002]), or malaria B- and T-cell epitopes (Nardin *et al.,* 2004). While mostly administered systemically, some VLPs-based vaccines already have been tested for mucosal administration.

G. DNA VACCINES

Immunisation with DNA represents a relatively new vaccination strategy that is based on a simple concept. DNA vaccines can be defined as antigen-encoding bacterial plasmids that are capable of inducing specific immune responses upon inoculation into a suitable host. Immunisation is accomplished by the uptake of purified plasmid in the host cells, where it persists extrachromosomally in the nuclei. Subsequent expression of protein results in the presentation of normally processed or modified forms of the protein to the immune system. In the host, native forms of the proteins have access to presentation pathways by class I major histocompatibility (MHC) antigens in addition to class II MHC presentation, which results in a balanced immune response. The use of pure plasmid DNA offers many advantages over other vaccine delivery vehicles. One of the greatest advantages is the ability of DNA vaccines to induce both humoral and cell-mediated immune responses, which is critical for protection from many diseases. There is also evidence that DNA vaccines can induce long-term immunity, which is a further requirement for vaccine efficacy. As the vector itself does not induce immune responses, DNA vaccines can be repeatedly administered without the interference of antibodies. From a technical viewpoint, DNA vaccines are easy to engineer, produce and purify, so new DNA vaccines can be constructed and evaluated in animal models within months. DNA vaccines are very stable and therefore have a long shelf life and can be transported without a cold chain. The safety of DNA vaccines has been established in various trials in several species including humans (Bagarazzi *et al.,* 1998; Kim *et al.,* 2001).

As soon as the concept of DNA immunisation began to be explored, this technology was found to be very effective in rodents, but initially did not perform as well in larger species. However, recent progress has resulted in the development of DNA vaccines in a number of target species (Carvalho *et al*., 2009; Redding & Weiner, 2009). Currently, four veterinary DNA vaccines have been licensed, against growth hormone releasing hormone for swine in Australia, infectious haematopoietic necrosis virus for salmon in Canada, WNV for horses and melanoma for dogs in the USA (Kutzler & Weiner, 2008). To achieve higher efficacy in large animal species, optimisation at various levels has been required, including (i) vector modifications; (ii) protein engineering to modify subcellular localisation; (iii) improvements in DNA delivery routes and methods; (iv) inclusion of adjuvants, as a gene or co-administered agent, and (v) antigen targeting to antigen-presenting cells (APCs). It is likely that the often unsatisfactory efficacy of DNA vaccines in large animals was caused by inefficient transfection, as well as 'immunological blandness', of the administered plasmids. The use of a needle-free vaccine delivery device was shown to reduce the effective dose of an experimental polyvalent DNA vaccine for avian influenza, and to rapidly deliver repeated injections in poultry (Rao *et al.,* 2009).

H. ANTIGEN DELIVERY AND MOLECULAR ADJUVANTS

Adjuvants are substances that enhance immune responses when co-administered with antigens. They are a critical component of killed (recombinant and subunit) vaccines, which are often poorly immunogenic. Adjuvants can be classified into two broad categories based on their presumed mechanism of action: i) delivery systems, and ii) immunostimulatory adjuvants. Delivery systems include many conventional adjuvants and numerous particulate adjuvants and will be discussed separately below.

Despite the importance of adjuvants in vaccines, their mechanisms of action remains poorly understood. Recent advances in the understanding of innate immunity have provided important clues on the molecular mechanisms of action of immunostimulatory adjuvants. In this regard, immune cells express a variety of receptors, collectively termed pattern recognition receptors (PRR) that broadly detect conserved microbial components referred to as pathogen-associated molecular patterns (PAMPs). A number of PRR have been described including toll-like receptors (TLR); e.g. TLR 9 recognises bacterial CpG nucleic acid motifs, natural agonist of TLR7/8, single-stranded viral RNA (oligoribonucleotides, ORN) strongly activate innate immune responses in mice, humans and are particularly potent in large animals; TLR4 agonist such as lipolysaccharide (LPS) that is known for its powerful immunostimulatory and adjuvant properties, but unfortunately this molecule is highly toxic; nucleotide oligomerisation domain (NOD)-like receptor (NLL), retinoic acid inducible gene (RIG)-like receptors (RLL), and C-type lectin receptors (CLR), all of which detect microbial components. Engagement of these receptors by their agonists leads to a cascade of molecular and cellular events that result in activation of innate immunity, which directs antigen-specific adaptive immunity. Of these receptors, TLR agonists are most widely explored and have shown great promise as adjuvants. Interestingly, the live-attenuated yellow fever vaccine 17D (YF-17D), one of the most successful vaccines available, activates TLR2, 7, 8 and 9 (Querec *et al.,* 2006), suggesting that the success of at least some of the live vaccines may be the result of their ability to activate TLRs. This has generated a great deal of interest in TLR agonist as adjuvants.

The existing paradigm in the veterinary vaccine industry of "one adjuvant-one vaccine," is driven partly by costs associated with including more than one adjuvant in a vaccine; however, it may severely limit the efficacy of potentially safe vaccine candidates, and may explain, at least in part, why some vaccines or adjuvants have only achieved suboptimal efficacy. Evidence is slowly accumulating to indicate that multiple adjuvants may offer more than can be achieved with a single adjuvant. For example, although CpG ODNs are a good adjuvant, they can have even greater adjuvant activity if formulated or coadministered with other compounds, such as particulates, mineral salts, saponins, liposomes, cationic peptides, polysaccharides and bacterial toxins and the synthetic polymers, polyphosphazenes (Wack *et al.,* 2008).

The adjuvant effect of microparticles has been known for some time and has been previously reviewed (Mutwiri *et al.,* 2005). Particulate delivery systems are thought to promote trapping and retention of antigens in local lymph nodes. In addition, microparticles facilitate antigen presentation by APCs via both MHC class I and MHC class II restricted processing and presentation pathways. One of the main advantages of microparticles for targeted antigen delivery is that they can be a flexible delivery platform that can be used to deliver both antigens and immunostimulatory molecules.

Other potential antigen delivery systems include polyphosphazenes, a class of synthetic polymers consisting of a backbone with alternating phosphorus and nitrogen atoms and organic side groups attached to each phosphorus (Mutwiri *et al.,* 2007). Immune stimulating complex (ISCOM), which is a small 40 nm nanoparticle composed of saponin (adjuvant), lipids and antigen, and has been described as an antigen delivery system because it not only has adjuvant activity and but also the ability to target APC (Morein *et al.,* 2004). A commercial ISCOM-based vaccine against equine influenza has been licensed for many years (Heldens *et al*., 2009).

I. VACCINE DELIVERY

Vaccine delivery comprises a diverse range of approaches with the overall goal of providing vaccines for mass vaccination during disease outbreaks and delivery of vaccines to wildlife. Oral vaccines used in rabies vaccination of wildlife such as foxes were initially based on attenuated rabies vaccine viruses such as the ERA strain, but concerns that these vaccines could rarely cause rabies (Fehlner-Gardiner *et al*., 2008) have largely lead to their replacement (http://ec.europa.eu/food/animal/diseases/eradication/rabies_pres_19.pdf). In Canada, a live adenovirus-vectored rabies vaccine with a good safety profile (Knowles *et al.,* 2009) is currently being used in rabies vaccination campaigns directed at controlling skunk and raccoon rabies (Rosatte *et al*., 2009). The live oral vaccinia-rabies glycoprotein (V-RG) vaccine is widely used elsewhere, and attempts are being made to optimise the vaccine baits for efficacy for other species including dogs (Cliquet *et al.,* 2008). Rabies infection in stray dogs and wildlife represents a serious problem for humans globally, and research for safer, more stable and efficacious live oral rabies vaccines continue (Faber *et al.,* 2009). Other possibilities for mass vaccination using edible plant-made vaccines have been actively investigated, but in spite of biotechnological advances in plant expression of vaccine antigens, no commercial products for oral use have been identified to date (Rice *et al.,* 2005).

CHAPTER 2.3.2.

THE ROLE OF OFFICIAL BODIES IN THE INTERNATIONAL REGULATION OF VETERINARY BIOLOGICALS

SUMMARY

The official control of veterinary biologicals is vested in various national and regional organisations that differ in their approach to ensuring the quality, safety and efficacy of the products. International harmonisation of regulations concerning biological products did not begin until well after those concerning chemically defined products. The first biological products for veterinary use were not manufactured and distributed until the end of the nineteenth century. They were often produced under unsophisticated conditions, and distributed or sold without any control other than those of their manufacturers. Later, each manufacturer developed its own standards. In Europe, these were subject to State controls as early as 1895 for certain diagnostic products (e.g. mallein, tuberculin) or vaccines. Gradually the conditions for international harmonisation of standards evolved, beginning with the comparative testing of products being issued by different European laboratories. It was only in the second half of the twentieth century that national laws covering veterinary biologicals were imposed. These demanded that precisely defined techniques be followed before biological products for veterinary use could receive relevant regulatory approval. This was followed by considerable efforts to harmonise these national regulations, first at the regional level (notably in Europe and the Americas) then at the global level, notably by the World Organisation for Animal Health (WOAH, founded as OIE) with the publication of the first edition of the WOAH Manual of Standards for Diagnostic Tests and Vaccines *in 1989.*

World-wide harmonisation of standards for veterinary biologicals will be of help to Chief Veterinary Officers who must follow the instructions given in the WOAH Terrestrial Animal Health Code*, as they apply to all biological products for use in international trade. It will also be of assistance to vaccine producers, who have expressed their wish for world-wide harmonisation of rules for relevant regulatory approvals so as to simplify and facilitate marketing of their products. Evidently, it will also be of interest to farmers and to consumers, who would benefit from the fact that the quality, safety and efficacy of the products that they use would have been assured to a uniformly high level.*

The different sections of this chapter will review and compare regulations from the regions of the world that have made most progress in this field and will describe current attempts at harmonising these regulations on an international scale.

Note: *In this chapter the term 'veterinary biological' will be taken to include vaccines for use in animals, antisera for use in animals, and* in-vivo *diagnostic preparations.*

A. REGULATION OF VETERINARY BIOLOGICALS: PRESENT SITUATION

1. In Japan

1.1. Introduction

Medicinal products that are exclusively used for animals, including veterinary biologicals, are under the jurisdiction of the Ministry of Agriculture, Forestry and Fisheries, and securing their quality, efficacy and safety is stipulated in the Law on Securing Quality, Efficacy and Safety of Products Including Pharmaceuticals and Medical devices (the Pharmaceutical and Medical Device Law) (Government of

Japan, Act No.145 of 10 August, 1960). Since 1972, registration procedures have been developed with the aim of rationalising the examination procedure and facilitating the acquisition of approval. These procedures are stipulated in the Pharmaceutical and Medical Device Law and other related regulations. Consequently, a speedy and simple examination procedure has been achieved with emphasis on the assurance of quality, safety and efficacy. The Food Safety Commission was established in the Cabinet Office, Government of Japan, in July 2003. In the case of approval examination, re-examination and re-evaluation, all veterinary vaccines, except products of dogs and cats, must comply with the Food Safety Basic Law.

1.2. Regulations governing the approval and quality assurance of veterinary biologicals

1.2.1. Application for relevant regulatory approval

A person intending to distribute veterinary biologicals shall obtain the license for marketing approval holders and the marketing approval for each biological from the Minister of Agriculture, Forestry and Fisheries after an intensive reviewing process by the National Veterinary Assay Laboratory (NVAL). The application for the marketing approval should be submitted with designated appended documents, such as those on clinical studies. Of the latter, the safety studies and clinical studies using the target animal species should have been performed in compliance with GLP (Good Laboratory Practice) and GCP (Good Clinical Practice). It is also required, as a condition of approval, that the manufacturing and quality control of the product complies with GMP (Good Manufacturing Practice). A marketing approval holder shall comply with the standard of GQP (Good Quality Practice) and the GVP (Good Vigilance Practice).

Regulatory approval to manufacture veterinary biologicals is issued by the Minister of Agriculture, Forestry and Fisheries and must be renewed every 5 years.

1.2.2. National assay

After receiving the marketing approval, each batch of the veterinary biological must be examined by the NVAL according to the procedures of the Assay Standard for Veterinary Biological Products, except for those approved as “seed-lot system”-based products (Anon, 2002b; Makie, 1998). A marketing approval holder must apply it to the national assay.

1.2.3. Re-examination and re-evaluation

Re-examination is performed on newly approved veterinary biologicals. Usually a field assessment of the veterinary vaccines is conducted over a period of 6 years following initial approval of the veterinary vaccines. During this investigation, the efficacy and the safety are re-examined.

Re-evaluation is performed on availability of approved products after marketing by order of the Minister of Agriculture, Forestry and Fisheries. This may happen when it is suspected that a veterinary biological does not conform to the latest standards of veterinary biological products.

1.2.4. Minimum requirement of veterinary biological products

The examinations provide information about the consistency of the manufacturing process and the quality of the product: manufacturing methods, properties of strains used for manufacturing, methods of quality control, methods of storage and shelf life, according to the standards given in the ‘Minimum Requirement of Veterinary Biological Products’ (Anon, 2002a). Any product that does not conform to these product standards cannot be manufactured, imported or marketed.

1.2.5. Cases of rejection of approval

When the quality of the veterinary biological that has been submitted for approval is found to be unsatisfactory, or its adverse effects are marked as compared with its indications, the product is judged to be of little value and approval is not given.

1.2.6. Cancellation of approvals

At the time of granting approval to market, the quality, safety and efficacy of the product are carefully examined with reference to the latest available technology. However, if scientific

knowledge acquired since the granting of approval indicates that there could be a health hazard associated with the product, re-examination and re-evaluation are performed and an order of 'cancellation of approval' may be made.

1.3. Procedure for marketing approval

When a person intends to market veterinary biologicals, an application for approval to market the veterinary drug must be submitted on a designated form to an official in charge of veterinary biologicals at the Ministry of Agriculture, Forestry and Fisheries. If the documentation is satisfactory, the application for approval to market, together with appended documents, are sent to and reviewed by the Secretariat of the Ministry of Agriculture, Forestry and Fisheries. At that time, a hearing may be conducted if necessary. The application is then discussed in the Pharmaceutical Affairs Sub-council, Pharmaceutical Affairs and Food Sanitation Council, and if any problems are not found, notice of approval to market the veterinary product is sent to the applicant.

2. In the European Union

2.1. Introduction

The pharmaceutical legislation of the European Union (EU), which has evolved over a 45-year period, covers both medicinal products for human and veterinary use. Harmonisation of requirements in the area of veterinary medicines began in 1981 with the adoption of Directives 81/851/EEC and 81/852/EEC, laying down common requirements for manufacturing and marketing authorisations, based on the evaluation of the quality, safety, and efficacy of the product. These Directives, and subsequent veterinary and human pharmaceutical legislation, were consolidated into Directive 2001/82/EC and 2001/83/EC for veterinary and human products, respectively. A series of detailed guidelines were first published in 1994 entitled 'Rules Governing Medicinal Products in the EU' (European Union, 1999). These have since been updated and describe in detail the legal basis for obtaining marketing authorisations, how dossiers should be compiled and how they should be assessed. These rules serve as extremely useful reference publications for any authority that is setting up a system for authorisation of veterinary biologicals. The rules were formally adopted and applied specifically to veterinary biologicals from 1993. Many additional measures were taken to further harmonise the procedures and the criteria for the evaluation of veterinary medicinal products, such as framework requirements and interpretive guidelines for their testing, principles and guidelines of GMP, and a Community procedure for the evaluation of high-technology products. However, granting of authorisations remained at the national level. As a consequence, although applications were evaluated on the basis of these harmonised criteria and procedures, and in some cases simultaneously by the authorities of the Member States, there were differences in the decisions reached by the Member States on individual products. This was why in 1990 the Commission proposed a new system for marketing authorisation for medicinal products, which was adopted by the Council of Ministers in 1993 and entered into force on 1 January 1995.

One of the first consequences was the creation of the European Medicines Evaluation Agency (EMEA), now the European Medicines Agency (EMA).

Legislation for veterinary products (Regulation 726/2004 and Directive 2004/28/EC) was published in May 2004. This legislation, for the main part, came into force in 2005 and resulted in a number of changes aimed at strengthening public and animal health, and environment protection by reinforcing requirements and controls. Directive 2001/82/EC already stated that the competent authorities cannot grant a marketing authorisation (MA) without having conducted a benefit–risk analysis. The document in the MA dossier must "demonstrate that the benefit bound to efficacy outweighs potential risk". But the relation between benefit and risk was not defined in that Directive. The new Directive gives the definition of the "risk–benefit balance": an evaluation of the positive therapeutic effects of the veterinary medicinal product in relation to the risk".

The risks concern:

i) The animal;

ii) The user of medicinal product;

iii) The consumer liable to ingest animal food containing medicinal products residues;

iv) The environment.

With the revision of the Directive, if no medicinal product is available for 3 consecutive years, its MA is secluded. Before the revision, the MA was renewed every 5 years. Now, a single renewal is required. The pharmacovigilance is reinforced.

Title IV of regulation 726/2004 related to responsibilities and administrative structure of the European Agency came into force in April 2004 in order to face the consequences of the enlargement of the EU.

Annex I of Directive 2001/82/EC was further amended to take account of scientific and technical progress. In particular, two new systems were introduced for particular immunological veterinary medicinal products and by derogation from the provisions of Title II, Part 2 Section C on active substances:

i) The first was based on the concept of a master file (vaccine antigen master file, VAMF), becoming a stand-alone part of the marketing authorisation application dossier for a vaccine, which contains all relevant information on quality concerning each of the active substances that are part of the veterinary medicinal product. The stand-alone part may be common to one or more monovalent or combined vaccines presented by the same applicant or marketing authorisation holder.

ii) The second was aimed at permitting authorisation of vaccines against antigenically variable viruses in a way that ensures that the most effective measures can be taken swiftly by the Community against the incursion or spread of three epizootic diseases (foot and mouth disease, avian influenza and bluetongue), leading to the concept of a multi-strain dossier. A multi-strain dossier means a single dossier containing the relevant data for a unique and thorough scientific assessment of the different options of strains or combinations of strains permitting the authorisation of vaccines against antigenically variable viruses.

In September 2015 the European Commission launched a revision of the legal framework for veterinary medicinal products in EU (i.e. directive 2001/82/EC). The purpose of this revision was to increase the availability of veterinary medicinal products, to reduce the administrative burden on commercial producers, to improve the functioning of the internal market for veterinary medicinal products and to assess the possibilities of having an improved response to antimicrobial resistance related to the use of veterinary medicines. The revision will contribute to the realisation of certain actions in the Animal Health Strategy.

2.2. The role of the European Medicines Agency

In 1995, a new European system for the authorisation of medicinal products came into force. After 10 years of cooperation between national registration authorities at the EU level and 4 years of negotiations, the Council of the EU adopted, in June 1993, three directives and one regulation, which together form the legal basis of the system (Brunko, 1997).

The EMEA was established by Council Regulation 2309/93/EEC of 22 July 1993 (*Official Journal* No. L214, 24.8.1993). In December 2009, the EMEA officially launched a new organisational structure and visual identity, and became the European Medicines Agency (EMA). This was the second major reorganisation of the Agency's services since it was established in 1995, and resulted from the expansion of the Agency's responsibilities and tasks, giving it a reinforced role in the protection of public and animal health in Europe.

This agency formulates opinions and, apart from the administrative staff and the management board, is composed of two scientific committees: the CHMP (Committee for Human Medicinal Products) in charge of medicinal products for humans and the CVMP (Committee for Veterinary Medicinal Products) in charge of medicinal products for use in animals.

The CVMP is responsible for the evaluation of applications for marketing authorisation for products derived from biotechnology, for productivity enhancers, new chemical entities and other innovative new products. In addition, the CVMP makes recommendations regarding MRLs (maximum residue limits) for substances used in food-producing animals, and manages referrals when EU issues such as

concerns over the safety or benefit–risk balance of a medicine or a class of medicines need to be resolved. To support its activities, the CVMP relies on a pool of experts put at the disposal of the agency by the EU Member States. These experts may participate in any of the CVMP working parties. Among the working parties, the Immunologicals Working Party (CVMP/IWP) advises the CVMP on general policy issues such as the elaboration and revision of guidelines on immunological veterinary medicinal products (IVMPs). A scientific advice working party foreseen in regulation 726/2004 has been created. The aim of this working party is to advise applicants during the development phase of a veterinary medicinal product. The CVMP prepares scientific guidelines in consultation with the national competent authorities of the EU Member States, to help applicants prepare marketing authorisation applications for medicinal products for veterinary use.

Guidelines are intended to provide a basis for the practical harmonisation of the manner in which the EU Member States and the Agency interpret and apply the detailed requirements for the demonstration of quality, safety and efficacy contained in the Community directives. They also help to ensure that applications for marketing authorisation are prepared in a manner that will be recognised as valid by the Agency.

Immunological guidelines are provided, for instance, for general items, quality, stability, efficacy, summary of product characteristics (SPC), multi-strain dossiers and availability (minor uses or minor species), and are available on the EMA website at: www.ema.europa.eu

2.3. Current European procedures for marketing authorisation

At the time of the revision of the Community Code in 2004, the difficulties encountered in practice as well as jurisprudentially precise details were taken into account and modifications to various Community procedures were adopted: tightening of the conditions of examination and the safeguard clause, official recognition of the coordination group for mutual recognition and decentralised procedures (veterinary), arbitration and creation of a new procedure (decentralised procedure, see below). These provisions were introduced by the Directive 2004/28/EC amending Directive 2001/82/EC.

Four registration procedures for human and veterinary medicinal products have become available through this new legislation:

1. The centralised procedure allows a unique marketing authorisation (MA) to be obtained and made available in all the Member States. This applies to high technology products defined in the annex to the Regulation. It is optional for innovative medicinal products. This procedure was extended to veterinary vaccines covering animal diseases that are subject to Community prophylactic measures.
2. The national procedure allows an MA to be obtained for a medicinal product in a single country or in a country that will be the origin of a mutual recognition procedure.
3. The mutual recognition procedure: applications for authorisation of a product may still be obtained in a single Member State (the 'Reference Member State') by means of a national procedure. Following approval in the Reference Member State, applications may be made, if desired, to other 'Concerned' Member States for identical authorisations to be granted on the basis of '*mutual recognition*'.
4. The decentralised procedure, which was introduced in Directive 2004/28/EC, is the addition of the national one and the mutual recognition procedure, i.e. it is based upon the principle of mutual recognition of national authorisations. At the beginning of this procedure, all Member States are associated, but assessment is conducted by one reference Member State chosen by the applicant.

The most important change is the compulsory aspect of *arbitrage* in the case of a disagreement between Member States during the mutual recognition or the decentralised procedures. If a Member State considers that there is a serious risk to public health, a pre-arbitrage procedure must be carried out. In such a situation, an MA holder cannot remove his/her demand. The arbitrage allows a decision to be made on whether there is a "serious risk" with the use of the medicinal product. Finally, the decision (to grant or refuse the MA) is harmonised throughout the community.

2.4. Manufacturing authorisation and batch release control

In accordance with Directive 2001/82/EC, authorisation is also required for the manufacture of veterinary medicinal products, including immunologicals. This directive provides for regular inspections and stipulates that manufacture must be supervised by a 'qualified person', who certifies that each batch is in conformity with the approved specifications for the product. For the implementation of these requirements, the Commission has adopted Directive 91/412/EEC relating to the principle and guidelines of GMP, and published a detailed guide on GMP developed by a group of pharmaceutical inspectors from the Member States (European Union, 1999: Volume 4).

The directive also establishes GMP for active starting materials for medicinal products. This provision is reinforced through the provision of the opportunity for Member States to carry out inspections of active materials destined for the manufacturers of veterinary medicinal products.

Manufacturers are required to have the services of a qualified person at their disposal to certify that each batch of product has been manufactured and checked in accordance with the conditions for marketing authorisation. This is a basic requirement of the pharmaceutical legislation. In the case of batches imported from third countries, each batch has to undergo a full qualitative and a quantitative analysis of at least the active ingredients in the first Member State of import into the EU, under the supervision of a qualified person. Until this control by the qualified person has been carried out, a batch cannot circulate within the EU without further control. When the certificate is released, no more controls are necessary. In the special case of immunological veterinary medicinal products, an additional step may be introduced. Article 82 of Directive 2001/82/EC, as amended by Directive 2004/28/EC, of the European Parliament and the Council allows, for reasons of human or animal health, a Member State to request samples of each batch of a given IVMP to be submitted to a Competent Authority (CA) for official testing by an Official Medicine Control laboratory (OMCL) before it is placed on the market and establishes the conditions under which a restricted test list can be applied. This is referred to as 'Official Control Authority Batch Release'. OCABR performed by any given Member State must be mutually recognised by all other member states requiring OCABR for that product.

Article 81 of Directive 2001/82/EC allows a Member State, where appropriate, to ask a MA holder to provide documentation to a control authority or an OMCL proving that control tests were carried out in accordance with the methods laid down in the MA dossier. This is referred to as an 'Official Batch Protocol Review'. A goodwill agreement has been adopted by the Veterinary Batch Release Network (VBRN) to mutually recognise Official Batch Protocol Review (OBPR) certificates between Member States provided the procedure and rules codified by the network are followed. This legislation concerns EU/EEA Member States and is also applied by any state having signed a formal agreement, which includes recognition of OCABR, with the EU. Currently, Switzerland has done so via a Mutual Recognition Agreement (MRA) (source EDQM).

2.5. The role of the European Pharmacopoeia

The Convention on the elaboration of a European Pharmacopoeia (or international treaty) adopted at the Council of Europe in 1964, laid the groundwork for the European Pharmacopoeia as a guarantee of the quality of medicines produced in Europe.

The European Pharmacopoeia Convention has now been signed by 37 Member States[1] and the EU; moreover 27 European and non-European countries[2], and the World Health Organisation (WHO) have observer status. Close relations are maintained with the regulatory authorities of the European

1 Austria, Belgium, Bosnia and Herzegovina, Bulgaria, Croatia, Cyprus, Czech Republic, Denmark, Estonia, Finland, Former Yugoslav Republic of Macedonia, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, Montenegro, Netherlands, Norway, Poland, Portugal, Romania, Serbia, Slovakia, Slovenia, Spain, Sweden, Switzerland, Turkey, Ukraine, United Kingdom and the European Union. Member States must apply the standards of the European Pharmacopoeia.

2 Albania, Algeria, Argentina, Armenia, Australia, Azerbaijan, Belarus, Brazil, Canada, China (People's Rep. of), Chinese Taipei (Food and Drug Administration), Georgia, Guinea, Israel, Kazakhstan, Korea (Rep. of), Madagascar, Malaysia, Moldova, Morocco, Russian Federation, Senegal, Singapore, South Africa, Syria, Tunisia, United States of America and the World Health Organization. Observer States do not have to apply the European Pharmacopoeia standards. Some of them apply the standards on a voluntary basis.

Economic Area, where integration is developing through contact with the EMA and the implementation of common directives and guidelines on medicines for human and veterinary use.

The European Pharmacopoeia consists of monographs describing individual quality standards (set of control tests applicable to one ingredient) and general quality standards applicable to families of ingredients or to dosage forms, as well as general methods of analysis. It defines the minimum acceptable standards for products to be authorised within the European Union because compliance with monographs is a mandatory requirement within Directive 2001/82/EC. This requires that products must comply with the relevant specific monograph where one exists or with the general monographs where one does not.

The European Directorate for the Quality of Medicines & Health Care (EDQM) is the administrative entity in the Council of Europe that provides the secretariat services for the European Pharmacopoeia. EDQM creates, maintains and distributes the international standard reagents referred to in monographs of the European Pharmacopoeia, including standards for veterinary biologicals.

In 1990, the European Pharmacopoeia co-founded, with the Japanese Pharmacopoeia and the United States (US) Pharmacopoeia, the Pharmacopoeial Discussion Group (PDG); this group is working assiduously for harmonisation at the global level.

The European Pharmacopoeia Commission adopted several harmonised texts for veterinary vaccines. The safety tests and the tests for increased virulence performed during development of the vaccines were harmonised in the framework of harmonisation with VICH (International Cooperation on Harmonisation of Technical Requirements for Registration of Veterinary Products; see below) Guidelines 41 and 44, and to ensure consistency with European regulations.

3. In the United States of America

3.1. Introduction

In the United States of America (USA), veterinary biologics or veterinary biological products are defined as all viruses, sera, toxins (excluding substances that are selectively toxic to microorganisms, e.g. antibiotics), or analogous products at any stage of production, shipment, distribution, or sale, that are intended for use in the treatment (prevention, diagnosis, management, or cure) of diseases of animals and that act primarily through the direct stimulation, supplementation, enhancement, or modulation of the immune system or immune response. The term biological products includes, but is not limited to, vaccines, bacterins, allergens, antibodies, antitoxins, toxoids, immunostimulants, certain cytokines, antigenic or immunising components of live organisms, and diagnostic components that are of natural or synthetic origin or that are derived from synthesising or altering various substances or components of substances such as microorganisms, genes or genetic sequences, carbohydrates, proteins, antigens, allergens, or antibodies.

3.2. Legal basis

The Virus/Serum/Toxin Act of 1913 (the 'VST Act'), as amended, 21 U.S.C. Sections 151 to 159, provides the legal authority for the regulation of immunologicals and biologicals for animal use in the USA. The regulatory programme implementing the requirements of the VST Act is administered by the Center for Veterinary Biologics (CVB), Animal and Plant Health Inspection Service (APHIS) of the United States Department of Agriculture (USDA). Administrative regulations, duly promulgated and with effect of law, are published in Title 9, Code of Federal Regulations, Parts 101 to 118 (2006). In addition, APHIS has issued programme guidance in CVB Notices, Veterinary Services Memoranda, Veterinary Biologics General Licensing Considerations, and the Veterinary Biologics Program Manual. These may be accessed on the CVB web site at www.aphis.usda.gov/vs/cvb.

The VST Act requires that products governed by the Act that enter channels of commerce be 'not worthless, contaminated, dangerous or harmful'. The regulatory scheme implementing these standards is structured to require manufacturers of these products to apply for licences prior to marketing, and to place certain evidentiary responsibilities on those applicants, i.e. manufacturers are required to demonstrate through the submission of certain information, research data, and test results that their

products are 'pure, safe, potent and efficacious'. The APHIS programme for immunologicals and biologicals for animal use regulates the manufacture and release of products on to the market through a system of licensing, inspection, testing and post-marketing surveillance that ensures that the statutory and regulatory standards are met.

3.3. Licensing and initial inspection

Any person or firm seeking to manufacture in the USA an immunological or biological for animal use must obtain from APHIS both a licence to manufacture at a specified facility (Establishment Licence), and a licence for every particular product to be manufactured (Product Licence). These licence requirements apply whether the product is to be released on to the US market or is to be exported to markets abroad. Typically, an applicant will request a facility licence at the same time as the licence for the first product. Once the facility licence and one product licence have been obtained, a firm that seeks to manufacture and market new products needs only to apply for additional product licences. A person or firm located overseas that seeks to market its product in the USA must also apply for marketing authorisation. In the case of an imported product, however, the authorisation is termed a 'permit' rather than a 'licence'.

To obtain a facility licence, the applicant must submit for approval the blueprint (that is, the architect's plan of the buildings) and blueprint legends for the facility. APHIS reviews these blueprints and legends to ensure that the facility will operate in a manner consistent with GMP. If the applicant subsequently makes any physical or operational changes to the facility, revised blueprints and legends must be submitted immediately.

To obtain a product licence, the applicant must establish the purity and identity of all master seeds and master cell stocks that will be used in the manufacture of the product, and must submit for approval a detailed outline of production. The outline of production includes not only the details of the method of product manufacture, but also a description of the procedures for collecting and submitting samples and for releasing batches. The applicant must also provide information regarding the professional and technical credentials of company personnel, and must identify a qualified individual (termed under US regulations as the 'government liaison') who acts as the official contact with CVB during the licensing process, and who is subsequently responsible for the submission of the firm's test reports in conjunction with the release of the product on to the market. The applicant is required to submit test data that demonstrate that the product produced in accordance with the outline is pure, safe, potent and efficacious. The applicant must submit to CVB laboratories samples of three consecutive batches of the product so that the results of the applicant's tests of the product can be confirmed.

Finally, before the facility or product licences are issued, the applicant's premises are subject to a comprehensive inspection by APHIS examiners. The inspection ensures that the facility is operating in a manner consistent with GMP by confirming that the establishment is configured in the manner set out in the approved blueprints and legends, that the production line is set up and operating in accordance with the approved outline of production, and that records are adequately kept and maintained for each step in production. The inspection also confirms that the applicant follows procedures consistent with GLPs, that the in-process and final product testing programme is conducted properly and appropriately documented, that the sampling is conducted properly, and that adequate procedures for determining and documenting the release of the product on to the market are in place.

3.4. Post-licensing inspection

Once a firm has been issued facility and product licences, APHIS will routinely conduct thorough follow-up inspections of the facility to ensure that the licensee continues to operate the establishment in accordance with the programme regulations and in the manner represented at the time of licensing. Post-licensing inspections are conducted unannounced periodically. If the licensee proposes any significant changes to the facility or to the method of production of a licensed product, APHIS retains the right to conduct a special inspection prior to approving the changes.

3.5. Testing

Each licensee is responsible for thoroughly testing all of its production processes and each serial (or lot) of every product prior to release on to the market. The type and amount of testing required

depends on the particular product, but is determined and approved by the regulatory authority prior to the issuing of the product licence. A qualified individual employed by the licensee ('government liaison') is responsible for selecting the samples to be tested, for monitoring the licensee's testing programme, and for certifying the test results to the regulatory authority.

At the same time that the firm selects its samples for its own in-house testing, it also selects samples to be submitted to the CVB laboratories. The CVB retains the right to conduct confirmatory testing. CVB then selects a percentage of the samples submitted for confirmatory testing to verify the accuracy and proficiency of the manufacturer's tests. The testing is conducted prior to marketing authorisation for each serial. By regulation, CVB policy stipulates that it is required to put its selected samples on test within 14 days of the date on which the samples are received; ordinarily, samples are put on test sooner than the 14-day limit so that the testing of production by the firm and the CVB proficiency testing programme are effectively being conducted at the same time.

When the firm receives the results of its own tests, the government liaison submits those results to the regulatory authority along with a batch release form, initiating the release procedure. If the batch has not been selected as part of the proficiency testing programme, or if it has been selected but the CVB tests confirm the company's test results, the release form is counter-signed by the regulatory authority completing the release procedure. If either the company tests or the proficiency tests indicate that the batch may be unsatisfactory, the batch is not eligible for release.

If the licensee makes a proposal to modify its facility or its operation in any way that could affect the purity, safety, potency or efficacy of the product, the regulatory authority may require the licensee to provide data demonstrating the purity, safety, potency and efficacy of the product as well as to submit samples of the product to CVB's laboratories for confirmatory testing.

3.6. Post-marketing surveillance

CVB operates a post-marketing surveillance programme to monitor the performance of products on the market. Under this programme, CVB typically learns of any problems relating to product quality through consumer reports or complaints, although the programme regulations also place an obligation on the licensee to inform CVB of any problem that comes to its attention regarding the purity, safety or potency of the product. CVB has the legal authority to intervene in the marketplace where there are serious concerns with respect to the purity, safety, potency or efficacy of the product.

B. COMPARISON OF EUROPEAN UNION AND UNITED STATES REGULATIONS

Veterinary biologicals must meet certain basic criteria, regardless of the Regulatory Agency overseeing their production. These criteria include:

- Safety: the product must be safe in the target species and, if live, in species exposed to shed organisms;
- Efficacy: the product should be effective according to claims indicated on the label;
- Quality: includes purity, potency and consistency;
- Purity: the product must be free from contaminating agents;
- Potency: each batch of product should be formulated, and tested, to ensure effectiveness and reproducibility of activity as demonstrated in the registration data.

Although, on a global basis, agencies and regulations differ, all strive to ensure that products offered to the end-consumer conform to these basic standards.

The EU uses a complete system that is a combination of GMP, including validated processes and specifications of materials, together with production methods that ensure the quality of the final product. In-process and batch controls (tests) constitute additional guarantees of the quality of IVMPs. The safety tests are conducted under GLP and the field efficacy tests under GCP. The USA defines acceptable manufacturing processes in the outline of production and detailed facility description (blueprints and blueprint legends), and relies on inspection and confirmatory testing to achieve the same goal. Although different, both systems are designed to allow only pure, safe, potent, and effective biologicals to be released to the consumer.

In addition to the data provided by the applicant, expert reports have to be included in the EU marketing authorisation application file (dossier). Each main section of the EU dossier, including analytical, safety and efficacy, must be reviewed by an independent expert. The assessment of the expert is included in the marketing authorisation file. No such system of third-party review exists under the USDA registration system with the exception of certain biotechnologically derived products.

There are many procedural differences between the EU and the USA. Harmonisation between the two systems should be established where possible, on the recognition of equivalence for tests and procedures that are performed to assess a vaccine and that ensure quality, safety and efficacy of the product. Mutual recognition agreements (MRAs) covering veterinary biologicals have been signed between the EU and Australia and between the EU and New Zealand. These MRAs are now at an operational stage. Progress on MRAs between the EU and the USA, regarding veterinary biologicals, is likely to take longer to achieve.

C. THE ROLE OF INTERNATIONAL ORGANISATIONS

Most nations have a range of official acts that regulate the sale and use of veterinary biologicals. Almost all of these acts stipulate 'minimum requirements' for quality, safety and efficacy of veterinary biologicals (mostly vaccines), to be tested at independent laboratories, usually under State supervision. These acts and tests may differ from one country to another, and they involve costs and restrictions for producers, users and testers.

Many of the vaccines described in this *Terrestrial Manual* are produced and/or used in countries that do not currently apply regimens of authorisation and testing as stringent as those described in this chapter. Nevertheless, it is useful to be aware of the regulations operating in different regions and, therefore, the testing and inspection that is likely to have been carried out there on a veterinary biological.

The idea of harmonising this testing to simplify and reduce costs on a regional, or even world scale, is not new, and much has been accomplished during the past 20 years. The purpose of this section is to review the current situation by describing the role of international organisations in the regulation of veterinary vaccines.

In this section the term 'international organisation' refers to those concerned with animal health on a world-wide scale (WOAH, the Food and Agriculture Organization of the United Nations [FAO] and the WHO).

1. The role of WOAH (World Organisation for Animal Health)

WOAH was founded, as OIE, in Paris in 1924 as the world organisation for animal health, and comprised 182 Member Countries in the year 2018. The principal aims of WOAH are: to ensure transparency in the global animal disease and zoonosis situation, to collect, analyse and disseminate scientific veterinary information, to provide expertise and encourage international solidarity in the control of animal diseases, within its mandate under the Agreement on Sanitary and Phytosanitary Measures (SPS Agreement) of the World Trade Organization (WTO), to safeguard world trade by publishing health standards for international trade in animals and animal products, to improve the legal framework and resources of national Veterinary Services and to provide a better guarantee of the safety of food of animal origin and to promote animal welfare through a science-based approach (Truszczynski & Blancou, 1992).

Within WOAH there are four Specialist Commissions: the Terrestrial Animal Health Standards Commission, which deals with the *Terrestrial Animal Health Code,* the Biological Standards Commission, the Scientific Commission for Animal Diseases and the Aquatic Animal Health Standards Commission (including diseases of molluscs and crustaceans). In addition, there is one Working Group: the Working Group on Wildlife.

Among the Specialist Commissions, the one most closely connected with standardisation is the Biological Standards Commission. This Commission establishes standards for diagnostic methods (including diagnostic preparations) and for vaccines. Its terms of reference reflect the Commission's obligation to participate in the standardisation of biological products, including vaccines used for prophylactic purposes. The Biological Standards Commission is responsible for the preparation of the WOAH *Manual of Diagnostic Tests and Vaccines for Terrestrial Animals*, and the organisation of Reference Laboratories for many of the diseases on the WOAH List.

However, full standardisation of vaccine testing can be achieved only when the necessary standards have been devised. It is hoped to reach the goal of standardisation and wide availability of standards through the participation of WOAH Reference Laboratories. In 2018, the WOAH has 182 Member Countries with a global network of 246 Reference Laboratories covering 105 diseases or topics in 35 countries, and 55 Collaborating Centres covering 49 topics in 28 countries. The functions and responsibilities of experts at the WOAH Reference Laboratories include the provision of a centre of excellence in a designated activity; standardisation of methods; preparation, storage and distribution of standard antisera, antigens and other reagents.

Among the WOAH Collaborating Centres, seven may be involved at some stage in veterinary vaccine control or harmonisation: the Collaborating Centre for Veterinary Medicinal Products in Fougères (France), the Collaborating Centre for ELISA (enzyme-linked immunosorbent assay) and Molecular Techniques in Animal Disease Diagnosis in Vienna (Austria), Collaborating Centre for Diagnosis and Control of Animal Diseases and Related Veterinary Product Assessment in Asia in Tokyo (Japan), the Collaborating Centre for the Diagnosis of Animal Diseases and Vaccine Evaluation in the Americas in Ames (USA), the Collaborating Centre for Development and Production of Vaccines, Pharmaceutical Products and Veterinary Diagnostic Systems using Biotechnology, Centro de Ingeniería Genética y Biotecnología, Havana (Cuba), the Collaborating Centre for Quality Control of Veterinary Vaccines, Pan-African Veterinary Vaccine Centre (Ethiopia) and the Collaborating Centre for Validation, Quality Assessment and Quality Control of Diagnostic Assays and Vaccine for Vesicular Diseases in Europe**,** Centre d'Etudes et de Recherches Vétérinaires et Agrochimiques de Ukkel (Belgium).

In 1994, following discussions with the International Technical Consultation on Veterinary Drug Registration (ITCVDR), WOAH set up an *ad hoc* Group on the Harmonisation of Veterinary Medicines, which was the first step towards the creation of the VICH (International Cooperation on Harmonisation of Technical Requirements for Registration of Veterinary Products) (see Section C.4 below).

In May 2003, the WOAH International Committee (now World Assembly) adopted a resolution entitled WOAH Procedure for Validation and Certification of Diagnostic Assays (Test Methods) for Infectious Animal Diseases. This resolution required the WOAH Director General to establish a WOAH registry for assays with levels of validation specified. Fitness for purpose is used as a criterion for validation.

2. The role of the Food and Agriculture Organization of the United Nations

FAO, established in 1945, is responsible for agricultural development and food production. The Animal Production and Health Division ('AGA') within the Agriculture Department is concerned with livestock development, and it includes the Animal Health Service ('AGAH'), the main role of which is to assist Member Countries in the control of animal diseases, with the aim of improving livestock production as an integral component of general social, economic and agricultural development. FAO's involvement in testing veterinary biologicals is primarily through its technical assistance system to Member Countries to set up and even execute independent quality control of vaccines and other biologicals. One example is FAO's assistance to the AU (African Union) in setting up a system for continental testing of veterinary vaccines, by the Pan African Veterinary Vaccine Center (PANVAC). FAO also commissions, at the request of Member Countries, initiatives for either quality assurance of vaccines and other biologicals or expert consultations on this subject, or publication of manuals on the production and quality control of vaccines. Furthermore, two auxiliary services can be asked to intervene on matters concerning these products, namely Codex Alimentarius and the Division of Nuclear Techniques in Food and Agriculture. The latter is operated jointly by FAO and the International Atomic Energy Agency (IAEA) based in Vienna (Austria). It has an Animal Production and Health Section, which assists veterinary services and research institutes in developing countries to establish radio-immunoassay (RIA) and ELISA techniques. Linked to this activity is a quality assurance scheme under which laboratories in receipt of FAO/IAEA ELISA kits are required to routinely monitor internal quality controls and to periodically (once or twice a year) test a batch of unknown samples, and to forward the results to IAEA. The overall aim is to provide assurance to all concerned that the results being generated through the use of such internationally standardised and validated kits can be relied upon as correct.

3. The role of the World Health Organization

Currently WHO is not directly involved in preparing international reference preparations (i.e. antigens or antibodies) for purely veterinary use, but has developed and still retains in the National Institute for Biological Standards and Control, Potter's Bar (UK) some materials related to purely veterinary diseases (e.g. Newcastle disease live vaccine, classical swine fever serum). WHO wishes to retain a role in this area in instances where the veterinary reference preparations and guidance documents have a direct relevance to human health (Joint

FAO/WHO Expert Committee on Brucellosis, 1986; Meslin *et al.,* 1996; WHO Expert Committee on Biological Standardisation, 1992; WHO Expert Committee on Rabies, 1992). This involves zoonotic and potentially zoonotic agents and other infectious agents of animal origin that are potential contaminants of biological products, whether these are vaccines produced in cell cultures or organs for xenotransplantation. At the meeting of the Expert Committee on Biological Standardization in October 1998, a review of currently retained international standards and reference preparations for veterinary medicine was carried out and a list of candidates for discontinuation, replacement and revision was suggested (Joint FAO/WHO Expert Committee on Brucellosis, 1986). The Expert Committee however decided to defer taking action on preparation of veterinary reference materials pending an evaluation by WHO with its partners in the veterinary field of the need for these various biological products. In addition, the present day topicality of certain preparations, especially veterinary vaccines against known zoonoses (e.g. anthrax, brucellosis) adopted and/or revised in the 1960s and 1970s, also needs to be evaluated.

The format of the list of Requirements for Biological Substances published as an Appendix to each report of the Expert Committee on Biological Standardization was revised in 1998 and should facilitate the retrieval of information and achieve the aim of improved transparency.

4. The role of VICH

4.1. What is VICH?

4.1.1. Short description of VICH

The International Cooperation on Harmonisation of Technical Requirements for Registration of Veterinary Medicinal Products (VICH) is an international programme aimed at providing guidance on the technical requirements for registration of veterinary medicinal products. VICH was established in 1996 as a means of collaboration, primarily between the regulatory authorities and the animal health industry of the EU, Japan and the USA. The regulatory authorities and animal health industry of Australia, New Zealand, Canada and South Africa also participate actively as VICH observer members. WOAH participates as an associate member in the VICH process with the goal of supporting and disseminating the outcomes at the global level.

4.1.2. Background and history

The initiative to begin the harmonisation process came in 1983 when the first International Technical Consultation on Veterinary Drug Registration (ITCVDR) was held. Since then a series of government and industry initiatives have been developed, culminating in the formation of the VICH.

The Codex Alimentarius formed a Committee on Residues of Veterinary Drugs in Foods in 1985. Standard requirements for veterinary product registration were adopted in Europe in 1981.

The US Food and Drug Administration and the European Commission have held regular bilateral meetings for the last decade to discuss common areas of interest. This has involved mutual exchange of guidelines for consultation.

The first International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) was held in Brussels in November 1991. The meeting brought together regulators and industry representatives from the USA, the EU and Japan to address quality, safety and efficacy requirements in the three regions.

Meetings on harmonisation of veterinary biologicals were held in Ploufragan, France, in January 1992, in Arlington, USA, in 1994 and in Singapore in 1995.

In January 1993 the GHOST (Global harmonisation of standards) discussion document was published by FEDESA[3]. It set out a programme for the international harmonisation of registration requirements for veterinary pharmaceuticals and biologicals.

Following discussions at ITCVDR and WOAH conferences, WOAH set up an *ad hoc* Group on harmonisation of veterinary medicinal products in 1994.

4.1.3. The creation and scope of VICH

Preparatory work for the establishment of VICH was carried out by this WOAH *ad hoc* Group. During 1994 and 1995, two meetings were held at which the scope of veterinary harmonisation was discussed and the membership and objectives of the VICH proposed.

On the subject of food safety standards, it was decided that the VICH should complement the work of Codex and JECFA[4]. Issues related to GLP and GMP that are already the subject of mutual agreements will not normally come within the remit of the VICH. Issues related to biologicals were considered appropriate to fall within the scope of VICH.

Fundamental to the selection of priority topics for consideration by the VICH was the discussion document prepared by COMISA for the Steering Committee. This report:

- assesses those ICH guidelines which could be adapted to the VICH programme;
- defines in detail areas of non-harmonisation between the EU, the US and Japan and provides a series of 'concept papers' on key topics; and
- puts forward preliminary suggestions for priority topics.

With all the ground-breaking work completed, the Steering Committee of the VICH held its first meeting in April 1996, at which the membership and the working procedures were agreed and a work programme established.

In November 2011, the VICH Outreach Forum was created to provide a basis for wider international harmonisation of registration requirements beyond the VICH member and observer regions and countries. The Forum aims to improve information exchange and raise awareness of VICH and understanding of VICH guidelines, thereby facilitating their wider adoption. The VICH Outreach Forum currently includes representatives from the regulatory authorities of many countries and three regional organisations for Africa, Asia and Americas.

4.1.4. The objectives of VICH

The objectives of the VICH are along the same lines as those of the ICH.

i) Establish and implement harmonised regulatory requirements for veterinary medicinal products in the VICH regions, which meet high quality, safety and efficacy standards and minimise the use of test animals and costs of product development.

ii) Provide a basis for wider international harmonisation of registration requirements.

iii) Monitor and maintain existing VICH guidelines, taking particular note of the International Conference on Harmonisation of Technical Requirements for the Registration of Pharmaceuticals for Human Use (ICH) work programme and, where necessary, update these VICH Guidelines.

iv) Ensure efficient processes for maintaining and monitoring consistent interpretation of data requirements following the implementation of VICH guidelines.

3 FEDESA: Fédération Européenne de la Santé Animale. In 2002, FEDESA became the International Federation for Animal Health (IFAH) and later HealthforAnimals. Now fulfils the role of VICH Secretariat.

4 JECFA: Joint FAO/WHO Expert Committee on Food Additives.

v) By means of a constructive dialogue between regulatory authorities and industry provide technical guidance enabling response to significant emerging global issues and science that impact on regulatory requirements within the VICH regions.

4.1.5. Progress toward achieving the VICH objectives

i) For veterinary immunologicals there is an ongoing programme of harmonisation in a number of areas including target animal safety studies, reversion to virulence and tests for the presence of *Mycoplasma*. To date only a relatively small number of VICH guidelines have been developed for veterinary biologicals and it is worth emphasising the difficulties in reaching agreement on veterinary biologicals between the three regions.

ii) The first two VICH Guidelines for veterinary biologicals were adopted in May 2003; one concerned the testing of residual formaldehyde and the other the testing of residual moisture. Several other Guidelines that apply to veterinary biologicals and all other veterinary medicinal products have also been adopted.

a) In 2013 and 2015 two new Guidelines were adopted: one concerning the harmonisation of criteria to waive target animal batch safety testing (TABST) for inactivated vaccines for veterinary biologicals (GL50), and one on the harmonisation of criteria to waive TABST for live vaccines (GL55).

b) In 2016, the Steering Committee (SC) adopted a Concept Paper on the development of further guidance on testing of veterinary vaccines for freedom from extraneous viruses. and a list of viruses. These two future VICH guidelines will be developed by taking into account the new relevant revised WOAH Chapter 1.1.9 *Tests for sterility and freedom from contamination of biological materials intended for veterinary use*.

Following the "VICH5"conference, held in Tokyo, Japan in 2015, the VICH Priorities Phase 4 document was published providing a vision for 2016–2020. To foster the already close collaboration with WOAH and in view of implementing the wider objective of international harmonisation, VICH supports the strategic activities of WOAH that are targeted at good governance of veterinary medicinal product in WOAH Member Countries.

More information is available at: https://vichsec.org/en/.

CONCLUSION

There is a clear intention to achieve greater international harmonisation of regulatory requirements for veterinary biologicals (Vannier *et al.,* 1997). Progress has already been achieved through international organisations to allow fair competition in the marketing of veterinary products. Although past efforts by international organisations have not resulted in a level of harmonisation sufficient to facilitate international trade, they have laid the groundwork for current efforts. National authorities recognise the advantages of harmonisation and are now committed to working toward this goal.

The efforts of international organisations have made the goal of harmonisation possible and have resulted in an organisation and process for proceeding toward this goal. Success in achieving this goal will depend on the willingness of participating national authorities to work together and accept the compromises that will be necessary to resolve the difficult scientific and policy issues.

CHAPTER 2.3.3.

MINIMUM REQUIREMENTS FOR THE ORGANISATION AND MANAGEMENT OF A VACCINE MANUFACTURING FACILITY

SUMMARY

This chapter sets out the management requirements for the manufacture of veterinary vaccines in accordance with Chapter 1.1.8 Principles of veterinary vaccine production. *Manufacturers should use the chapter as a basis for the elaboration of specific rules adapted to their individual needs. Many of the general principles of laboratory management set out in Chapter 1.1.1* Management of veterinary diagnostic laboratories *are applicable to vaccine production, including accountability, executive management, infrastructure, human resources and compliance.*

There should be sufficient qualified personnel to carry out all the tasks that are the responsibility of the manufacturer. Individual responsibilities should be clearly understood by the individuals and recorded. All personnel should be aware of the principles of Good Manufacturing Practice (GMP) that affect them and receive initial and continuing training, including hygiene instructions, relevant to their needs. Appropriate procedures should be in place for biorisk management, to protect the personnel, to prevent hazardous biological agents from leaving the plant, and to prevent contamination of products within the plant.

Premises and equipment should be located, designed, constructed, adapted and maintained to suit the operations. Their layout and design should aim to minimise the risk of errors and permit effective cleaning and maintenance in order to avoid cross-contamination, build-up of dust or dirt and, in general, any adverse effect on the quality of products.

Good documentation (including electronic records) constitutes an essential part of the quality assurance system and is key to operating in compliance with GMP requirements. The types of documents and electronic media used should be fully defined in the manufacturer's quality management system. The main objective of the system of documentation should be to establish, control, monitor and record all activities that directly or indirectly impact on the quality of products. The quality management system should include sufficient detail to facilitate a common understanding of the requirements, in addition to providing sufficient records of processes and evaluation of observations.

Any outsourced activity should be appropriately defined, agreed and controlled in order to avoid misunderstandings that could result in a product or operation of unsatisfactory quality. Written contracts should cover outsourced activities, products or operations to which they are related, and any connected technical arrangements. All arrangements for the outsourced activities including any proposed changes in technical or other aspects should be in accordance with regulations in force, and the marketing authorisation for the product concerned. Where the marketing authorisation holder and the manufacturer are not the same, appropriate arrangements should be in place to take into account the principles described in this chapter.

All complaints and other information concerning potentially defective products should be reviewed carefully following written procedures. A system should be in place to evaluate complaints and, if necessary, initiate a recall from the market promptly and effectively for products known or suspected to be defective.

Self-inspections should be conducted in order to monitor the implementation and compliance with GMP principles, and to propose necessary corrective measures.

1. Rules for personnel

The establishment and maintenance of a satisfactory system of quality assurance and the correct manufacture of veterinary vaccines relies upon people. For this reason, there must be sufficient qualified personnel to carry out all the tasks that are the responsibility of the manufacturer. Individual responsibilities should be clearly understood by the individuals and recorded. All personnel should be aware of the principles of Good Manufacturing Practices (GMP) that affect them and receive initial and continuing training, including hygiene instructions, relevant to their needs.

1.1. General rules

i) The manufacturer should have an adequate number of personnel with the necessary qualifications and practical experience. The responsibilities placed on any one individual should not be so extensive as to present any risk to quality.

ii) The manufacturer must have an organisation chart. People in responsible positions should have specific duties recorded in written job descriptions and adequate authority to carry out their responsibilities. Their duties may be delegated to designated deputies of a satisfactory qualification level. There should be no gaps or unexplained overlaps in the responsibilities of those personnel concerned with the application of GMP.

1.1.1. Key personnel

i) Key personnel include the head of production, the head of quality control, the head of packaging and distribution, the head of technical services and the person(s) responsible for the batch release. Normally key posts should be occupied by full-time personnel. The heads of production and quality control should be held by different individuals, independent from each other. In large organisations, it may be necessary to delegate some of the functions.

1.1.2. Training

i) The manufacturer should provide training for all the personnel whose duties take them into production areas or into control laboratories (including the technical, maintenance and cleaning personnel), and for other personnel whose activities could affect the quality of the product.

ii) Besides the basic training on the theory and practice of GMP, newly recruited personnel should receive training appropriate to the duties assigned to them. Continuing training should also be given, and its practical effectiveness should be periodically assessed. Training programmes should be available, approved by a qualified person. Training records should be kept.

iii) Personnel working in areas where contamination is a hazard, e.g. clean areas or areas where highly active, toxic, infectious or sensitising materials are handled, should be given specific training (see Section 2.4 *Specific requirements for vaccine production*).

iv) Visitors or untrained personnel should, preferably, not be taken into the production and quality control areas. If this is unavoidable, they should be given information in advance, particularly about personal hygiene and the prescribed protective clothing. They should be closely supervised.

v) The concept of quality assurance and all the measures capable of improving its understanding and implementation should be fully discussed during the training sessions.

1.1.3. Personal hygiene

i) Detailed hygiene programmes should be established and adapted to the different needs within the factory. They should include procedures relating to the health, hygiene practices and clothing of personnel. These procedures should be understood and followed in a very strict way by every person whose duties take him into the production and control areas. Hygiene programmes should be promoted by management and widely discussed during training sessions.

ii) All personnel should receive a medical examination upon recruitment. It must be the manufacturer's responsibility that there are instructions ensuring that health conditions that can be of relevance to the quality of products come to the manufacturer's knowledge. After the first medical examination, examinations should be carried out when necessary for the work and personal health.

iii) Steps should be taken to ensure as far as is practicable that no person affected by an infectious disease or having open lesions on the exposed surface of the body is engaged in the manufacture of vaccines.

iv) Every person entering the manufacturing areas should wear protective garments appropriate to the operations to be carried out.

v) Eating, drinking, chewing or smoking, or the storage of food, drink, smoking materials or personal medication in the production and storage areas should be prohibited. In general, any unhygienic practice within the manufacturing areas or in any other area where the product might be adversely affected should be forbidden.

vi) Direct contact should be avoided between the operator's hands and the exposed product as well as with any part of the equipment that comes into contact with the products.

vii) Personnel should be instructed to use the hand-washing facilities.

viii) Any specific requirements for the manufacture of aseptic or sterile preparations related to production are covered in 2.4 *Specific requirements for vaccine production*.

1.2. Specific rules for personnel involved in the manufacture of vaccines

i) All personnel (including those concerned with cleaning and maintenance) employed in areas where immunological products are manufactured should be given training in and information on hygiene and microbiology. They should receive additional training specific to the products with which they work.

ii) Responsible personnel should be formally trained in some or all of the required fields.

iii) Personnel should be protected against possible infection with the biological agents used in manufacture. In the case of biological agents known to cause disease in humans, adequate measures should be taken to prevent infection of personnel working with the agent or with experimental animals.

iv) Where relevant, the personnel should be vaccinated and subject to medical examination.

v) Adequate measures should be taken to prevent biological agents being taken outside the manufacturing plant by personnel acting as a carrier. Dependent on the type of biological agent, such measures may include complete change of clothes and compulsory showering before leaving the production area.

vi) For immunological products, the risk of contamination or cross-contamination by personnel is particularly important.

vii) Prevention of contamination by personnel should be achieved by a set of measures and procedures to ensure that appropriate protective clothing is used during the different stages of the production process.

viii) Prevention of cross-contamination by personnel involved in production should be achieved by a set of measures and procedures to ensure that they do not pass from one area to another unless they have taken appropriate measures to eliminate the risk of contamination. In the course of a working day, personnel should not pass from areas where contamination with live micro-organisms is likely or where animals are housed to premises where other products or organisms are handled. If such passage is unavoidable, clearly defined decontamination procedures, including change of clothing and shoes, and, where necessary, showering, should be followed by staff involved in any such production.

ix) Personnel entering a contained area where organisms had not been handled in open circuit operations in the previous 12 hours to check on cultures in sealed, surface decontaminated flasks would not be regarded as being at risk of contamination, unless the organism involved was an exotic.

2. Requirements for premises and equipment

Premises and equipment must be located, designed, constructed, adapted and maintained to suit the operations to be carried out. Their layout and design must aim to minimise the risk of errors and permit effective cleaning and maintenance in order to avoid cross-contamination, build-up of dust or dirt and, in general, any adverse effect on the quality of products.

Premises and equipment used for critical operations must be qualified[1].

Added requirements for premises and equipment used in aseptic preparations are given in 2.4 *Specific requirements for vaccine production.*

2.1. General

i) Premises should be situated in an environment which, when considered together with measures to protect the manufacture, presents minimal risk of causing contamination of materials or products. Research and development activities associated with organisms not authorised to be handled in the premises must be carried out in buildings completely separated from the manufacturing facility.

ii) Premises should be carefully maintained, ensuring that repair and maintenance operations do not present any hazard to the quality of products. They should be cleaned and, where applicable, disinfected according to detailed written procedures.

iii) Lighting, temperature, humidity and ventilation should be appropriate and such that they do not adversely affect, directly or indirectly, either the medicinal products during their manufacture and storage, or the accurate functioning of equipment.

iv) Premises should be designed and equipped so as to afford maximum protection against the entry of insects or other animals.

v) Steps should be taken in order to prevent the entry of unauthorised people. Production, storage and quality control areas should not be used as a right of way by personnel who do not work in them.

2.2. Storage areas

i) Storage areas should be of sufficient capacity to allow orderly storage of the various categories of materials and products: starting and packaging materials, intermediate, bulk and finished products, products in quarantine, released, rejected, returned or recalled.

ii) Storage areas should be designed or adapted to ensure good storage conditions. In particular, they should be clean and dry and maintained within acceptable temperature limits. Where special storage conditions are required (e.g. temperature, humidity) these should be validated, checked and monitored.

iii) Receiving and dispatch bays should protect materials and products from the weather. Reception areas should be designed and equipped to allow containers of incoming materials to be cleaned where necessary before storage.

1 This qualification may be done according to the rules laid down in the PIC/S (see References).

iv) Where quarantine status is ensured by storage in separate areas, these areas must be clearly marked and their access restricted to authorised personnel. Any system replacing the physical quarantine should give equivalent security.

v) There should normally be a separate sampling area for starting materials. If sampling is performed in the storage area, it should be conducted in such a way as to prevent contamination or cross-contamination.

vi) Segregated areas should be provided for the storage of rejected, recalled or returned materials or products.

vii) Highly active materials or products should be stored in safe and secure areas.

viii) Printed packaging materials are considered critical to the conformity of the vaccine and special attention should be paid to the safe and secure storage of these materials.

2.3. Production premises – general requirements

i) Premises should preferably be laid out in such a way as to allow the production to take place in areas connected in a logical order corresponding to the sequence of the operations and to the requisite cleanliness levels.

ii) The adequacy of the working and in-process storage space should permit the orderly and logical positioning of equipment and materials so as to minimise the risk of confusion between different medicinal products or their components, to avoid cross-contamination and to minimise the risk of omission or wrong application of any of the manufacturing or control steps.

iii) Where starting and primary packaging materials, intermediate or bulk products are exposed to the environment, interior surfaces (walls, floors and ceilings) should be smooth, free from cracks and open joints, and should not shed particulate matter and should permit easy and effective cleaning and, if necessary, disinfection.

iv) Pipework, light fittings, ventilation points and other services should be designed and sited to avoid the creation of recesses that are difficult to clean. As far as possible, for maintenance purposes, they should be accessible from outside the manufacturing areas.

v) Drains should be of adequate size, and have trapped gullies. Open channels should be avoided where possible, but if necessary, they should be shallow to facilitate cleaning and disinfection.

vi) Production areas should be effectively ventilated, with air control facilities (including temperature and, where necessary, humidity and filtration) appropriate both to the products handled, to the operations undertaken within them and to the external environment.

vii) Weighing of starting materials usually should be carried out in a separate weighing room designed for that use.

viii) In cases where dust is generated (e.g. during sampling, weighing, mixing and processing operations, packaging of dry products), specific provisions should be taken to avoid cross-contamination and facilitate cleaning.

ix) Premises for the packaging of vaccines should be specifically designed and laid out so as to avoid mix-ups or cross-contamination.

x) Production areas should be well lit, particularly where visual on-line controls are carried out.

xi) In-process controls may be carried out within the production area provided they do not carry any risk for the production.

2.3.1. Ancillary areas

i) Rest and refreshment rooms should be separate from other areas.

ii) Facilities for changing clothes and for washing and toilet purposes should be easily accessible and appropriate for the number of users. Toilets should not directly communicate with production or storage areas.

iii) Maintenance workshops should as far as possible be separated from production areas. Whenever parts and tools are stored in the production area, they should be kept in rooms or lockers reserved for that use.

2.3.2. Quality control areas

i) Normally, quality control laboratories should be separated from production areas. This is particularly important for laboratories for the control of biologicals, microbiologicals and radioisotopes, which should also be separated from each other.

ii) Control laboratories should be designed to suit the operations to be carried out in them. Sufficient space should be given to avoid mix-ups and cross-contamination. There should be adequate suitable storage space for samples and records.

iii) Separate rooms may be necessary to protect sensitive instruments from vibration, electrical interference, humidity, etc.

iv) Special requirements are needed in laboratories handling particular substances, such as biological or radioactive samples.

v) Animal houses should be well isolated from other areas, with separate entrance (animal access) and air handling facilities.

2.4. Specific requirements for vaccine production

2.4.1. Production areas

i) Premises should be designed in such a way as to control both the risk to the product and to the environment. This can be achieved by the use of containment, clean, clean or contained or controlled areas[2].

ii) Live biological agents should be handled in contained areas. The level of containment should depend on the pathogenicity of the micro-organism and whether it has been classified as exotic.

iii) Inactivated biological agents should be handled in clean areas. Clean areas should also be used when handling non-infected cells isolated from multicellular organisms and, in some cases, filtration-sterilised media.

iv) Open circuit operations involving products or components not subsequently sterilised should be carried out within a laminar air flow work station according to the rules for aseptic preparation.

v) Other operations where live biological agents are handled (quality control, research and diagnostic services, etc.) should be appropriately contained and separated if production operations are carried out in the same building. The level of containment should depend on the pathogenicity of the biological agent and whether they have been classified as exotic. Whenever diagnostic activities are carried out, there is the risk of introducing highly pathogenic organisms. Therefore, the level of containment should be adequate to cope with all such risks. Containment may also be required if quality control or other activities are carried out in buildings in close proximity to those used for production.

vi) Containment premises should be easily disinfected and should have the following characteristics:

a) the absence of direct venting to the outside;

2 Guidance on the qualification of the clean areas is given in ISO 14644 and described in the PIC/S GMP Guide (see References).

b) a ventilation system with air at negative pressure. Air should be extracted through HEPA (high-efficiency particulate air) filters and not be re-circulated except to the same area, and provided further HEPA filtration is used (normally this condition would be met by routing the re-circulated air through the normal supply HEPAs for that area). However, recycling of air between areas may be permissible provided that it passes through two exhaust HEPAs, the first of which is continuously monitored for integrity, and there are adequate measures for safe venting of exhaust air should this filter fail;

c) air from manufacturing areas used for the handling of exotic organisms should be vented through two sets of HEPA filters in series, and that from production areas not re-circulated;

d) a system for the collection and disinfection of liquid effluents (see Section 2.4.4 *Disinfection – waste disposal*);

e) changing rooms designed and used as air locks, and equipped with washing and showering facilities if appropriate. Air pressure differentials should be such that there is no flow of air between the work area and the external environment or risk of contamination of outer clothing worn outside the area;

f) an air lock system for the passage of equipment, which is constructed so that there is no flow of contaminated air between the work area and the external environment or risk of contamination of equipment within the lock. The air lock should be of a size that enables the effective surface decontamination of materials being passed through it. Consideration should be given to having a timing device on the door interlock to allow sufficient time for the decontamination process to be effective.

g) in many instances, a barrier double-door autoclave for the secure removal of waste materials and introduction of sterile items.

vii) Water treatment plants and distribution systems should be designed, constructed and maintained so as to ensure a reliable source of water of an appropriate quality. They should not be operated beyond their designed capacity. Water for injections should be produced, stored and distributed in a manner that prevents microbial growth, for example by constant circulation at a temperature above 70°C.

viii) Equipment passes and changing rooms should have an interlock mechanism or other appropriate system to prevent the opening of more than one door at a time. Changing rooms should be supplied with air filtered to the same standard as that for the work area, and equipped with air extraction facilities to produce an adequate air circulation independent of that of the work area. Equipment passes should normally be ventilated in the same way, but unventilated passes, or those equipped with supply air only, may be acceptable.

ix) Production operations such as cell maintenance, media preparation, virus culture, etc., likely to cause contamination should be performed in separate areas. Animals and animal products should be handled with appropriate precautions.

x) Production areas where biological agents particularly resistant to disinfection (e.g. spore forming bacteria) are handled should be separated and dedicated to that particular purpose until the biological agents have been inactivated.

xi) With the exception of blending and subsequent filling operations (for example with multi-valent vaccines), one biological agent only should be handled at a time within an area.

xii) Production areas should be designed to permit disinfection between campaigns, using validated methods.

xiii) Production of biological agents may take place in controlled areas provided it is carried out in totally enclosed and heat-sterilised equipment, all connections being also heat sterilised after making and before breaking. It may be acceptable for connections to be made under local laminar air flow provided these are few in number and proper aseptic techniques are used and there is no risk of leakage. The sterilisation parameters used before breaking the connections must be validated for the organisms being used. Different products may be placed in different biogenerators (fermenters), within the same area, provided that there is

no risk of accidental cross-contamination. However, organisms generally subject to special requirements for containment should be in areas dedicated to such products.

xiv) Access to manufacturing areas should be restricted to authorised personnel. Clear and concise written procedures should be posted as appropriate.

xv) The manufacturing site and buildings should be described in sufficient detail (by means of plans and written explanations) so that the designation and conditions of use of all the rooms are correctly identified as well as the biological agents that are handled in them. The flow of people and product should also be clearly marked.

xvi) The activities carried out in the vicinity of the site should also be indicated.

xvii) Plans of contained or clean area premises should describe the ventilation system indicating inlets and outlets, filters and their specifications, the number of air changes per hour, and pressure gradients. They should indicate which pressure gradients are monitored by pressure indicator.

2.4.2. Animals and animal houses

i) Animal houses should be separated from the other production premises and suitably designed.

ii) The sanitary status of the animals used for production should be defined, monitored, and recorded. Some animals should be handled as defined in specific monographs (e.g. specific pathogen free [SPF] flocks).

iii) Animals, biological agents, and tests carried out should be the subject of an identification system so as to prevent any risk of confusion and to control all possible hazards.

iv) Animal houses where animals intended or used for production are accommodated, should be provided with the appropriate containment or clean area measures, and should be separate from other animal accommodation.

v) Animal houses where animals used for quality control, involving the use of pathogenic biological agents, are accommodated, should be adequately contained.

vi) The animal species accommodated in the animal houses or otherwise on the site should be identified.

2.4.3. Equipment

i) The equipment used should be designed and constructed so that it meets the particular requirements for the manufacture of each product.

ii) Before being put into operation the equipment should be qualified and validated and subsequently be regularly maintained and validated.

iii) Where appropriate, the equipment should ensure satisfactory primary containment of the biological agents.

iv) Where appropriate, the equipment should be designed and constructed as to allow easy and effective decontamination or sterilisation.

v) Closed equipment used for the primary containment of the biological agents should be designed and constructed as to prevent any leakage or the formation of droplets and aerosols.

vi) Inlets and outlets for gases should be protected so as to achieve adequate containment, e.g. by the use of sterilising hydrophobic filters.

vii) The introduction or removal of material should take place using a sterilisable closed system, or possibly in an appropriate laminar air flow.

viii) Equipment where necessary should be properly sterilised before use, preferably by pressurised dry steam. Other methods can be accepted if steam sterilisation cannot be used because of the nature of the equipment. It is important not to overlook such individual items as bench centrifuges and water baths.

ix) Equipment used for purification, separation or concentration should be sterilised or disinfected at least between use for different products. The effect of the sterilisation methods on the effectiveness and validity of the equipment should be studied in order to determine the life span of the equipment.

x) All sterilisation procedures should be validated.

xi) Equipment should be designed so as to prevent any mix-up between different organisms or products. Pipes, valves and filters should be identified as to their function.

xii) Separate incubators should be used for infected and non-infected containers and also generally for different organisms or cells. Incubators containing more than one organism or cell type will only be acceptable if adequate steps are taken to seal, surface decontaminate and segregate the containers.

xiii) Culture vessels, etc., should be individually labelled. The cleaning and disinfection of the items can be particularly difficult and should receive special attention.

xiv) Equipment used for the storage of biological agents or products should be designed and used in such a manner as to prevent any possible mix-up. All stored items should be clearly and unambiguously labelled and in leak-proof containers. Items such as cells and organisms seed stock should be stored in dedicated equipment.

xv) Relevant equipment, such as that requiring temperature control, should be fitted with recording or alarm systems.

xvi) To avoid breakdowns, a system of preventive maintenance, together with trend analysis of recorded data, should be implemented.

xvii) The loading of freeze dryers requires an appropriate clean or contained area. Unloading freeze dryers contaminate the immediate environment. Therefore, for single-ended freeze dryers, the clean room should be decontaminated before a further manufacturing batch is introduced into the area, unless this contains the same organisms, and double door freeze dryers should be sterilised after each cycle unless opened in a clean area.

xviii) Sterilisation of freeze dryers should be done before use, preferably by pressurised dry steam. In case of campaign working, they should at least be sterilised after each campaign.

2.4.4. Disinfection – waste disposal

i) Disinfection or wastes and effluents disposal may be particularly important in the case of manufacture of immunological products. Careful consideration should therefore be given to procedures and equipment aiming at avoiding environmental contamination as well as to their validation or qualification.

3. Rules governing documentation

Documentation relating to the premises should be readily available in a **Site Master File**.

3.1. Principle

Good documentation constitutes an essential part of the quality assurance system and is key to operating in compliance with GMP requirements. The various types of documents and media used should be fully defined in the manufacturer's quality management system. Documentation may exist in a variety of forms, including paper-based, electronic or photographic media. The main objective of the system of documentation used must be to establish, control, monitor and record all activities that directly or indirectly impact on all aspects of the quality of products. The quality management system should include sufficient instructional detail to facilitate a common understanding of the requirements, in addition to providing for sufficient recording of the various processes and evaluation of any observations, so that on-going application of the requirements may be demonstrated.

There are two primary types of documentation used to manage and record GMP compliance: instructions (directions, requirements) and records or reports.

Suitable controls should be implemented to ensure the accuracy, integrity, availability and legibility of documents. Instruction documents should be free from errors and available in writing. This includes electronic records from which data may be rendered in a human readable form.

3.2. Required documentation

i) **Site Master File:** a document describing the GMP related activities of the manufacturer.

3.2.1. Instructions

i) **Specifications** describe in detail the requirements with which the products or materials used or obtained during manufacture have to conform. They serve as a basis for quality evaluation.

ii) **Manufacturing composition, processing, packaging and testing instructions** provide detail all the starting materials, equipment and computerised systems (if any) to be used and specify all processing, packaging, sampling and testing instructions. In-process controls and process analytical technologies to be employed should be specified where relevant, together with acceptance criteria.

iii) **Protocols** give instructions for performing and recording certain discreet operations.

iv) **Technical agreements** are agreed between contract givers and acceptors for outsourced activities.

3.2.2. Records or Reports

i) **Records** provide evidence of various actions taken to demonstrate compliance with instructions, including activities, events, investigations, and in the case of manufactured batches a history of each batch of product, from initiation of manufacture to final distribution. Records include the raw data that is used to generate other records. For electronic records regulated users should define which data are to be used as raw data. At least, all data on which quality decisions are based should be defined as raw data

ii) **Certificates of analysis** provide a summary of testing results on samples of products or materials together with the evaluation for compliance to a stated specification.

iii) **Reports** document the conduct of particular exercises, projects or investigations, together with results, conclusions and recommendations.

3.3. Generation and control of documentation

i) All types of document should be defined and adhered to. The requirements apply equally to all forms of document media types. Complex systems need to be understood, well documented, validated, and adequate controls should be in place. Many documents (instructions or records) may exist in hybrid forms, i.e. some elements as electronic and others as paper based. Relationships and control measures for master documents, official copies, data handling and records need to be stated for both hybrid and homogenous systems. Appropriate controls for electronic documents such as templates, forms, and master documents should be implemented. Appropriate controls should be in place to ensure the integrity and authenticity of the record throughout the retention period.

ii) Documents should be designed, prepared, reviewed, and distributed with care. They should comply with the relevant parts of product specification files, manufacturing and marketing authorisation dossiers, as appropriate. The reproduction of working documents from master documents should not allow any error to be introduced through the reproduction process.

iii) Documents containing instructions should be approved, signed and dated by appropriate and authorised persons. Documents should have unambiguous contents and be uniquely identifiable. The effective date should be defined.

iv) Documents containing instructions should be laid out in an orderly fashion and be easy to check. The style and language of documents should fit with their intended use. Standard Operating Procedures (SOPs), work instructions and methods should be written in an imperative mandatory style.

v) Documents within the quality management system should be regularly reviewed and kept up-to-date.

vi) Documents should not be hand-written; although, where documents require the entry of data, sufficient space should be provided for such entries.

3.4. Good documentation practices

i) Handwritten entries should be made in clear, legible, indelible way.

ii) Records should be made or completed at the time each action is taken and in such a way that all significant activities concerning the manufacture of vaccines are traceable.

iii) Any alteration made to the entry on a document should be signed and dated; the alteration should permit the reading of the original information. Where appropriate, the reason for the alteration should be recorded.

3.5. Retention of documents

i) It should be clearly defined which record is related to each manufacturing activity and where this record is located. Secure controls must be in place to ensure the integrity of the record throughout the retention period and validated where appropriate.

ii) Specific requirements apply to batch documentation that must be kept for 1 year after expiry of the batch to which it relates or at least 5 years after certification of the batch by the authorised person, whichever is the longer. For investigational vaccines, the batch documentation must be kept for at least 5 years after the completion or formal discontinuation of the last clinical trial in which the batch was used.

For other types of documentation, the retention period will depend on the business activity that the documentation supports. Critical documentation, including raw data (for example relating to validation or stability), which supports information in the marketing authorisation should be retained whilst the authorisation remains in force. It may be considered acceptable to retire certain documentation (e.g. raw data supporting validation reports or stability reports) where the data has been superseded by a full set of new data.

More information and details can be found on documentation within the PIC/S GMP guide (PIC/S, PE 009-11 [Part I], see References).

4. Rules governing outsourced activities

4.1. Principle

Any activity that is outsourced should be appropriately defined, agreed and controlled in order to avoid misunderstandings that could result in a product or operation of unsatisfactory quality.

4.2. General

i) There should be a written contract covering the outsourced activities, the products or operations to which they are related, and any technical arrangements made in connection with it.

ii) All arrangements for the outsourced activities including any proposed changes in technical or other arrangements should be in accordance with regulations in force, and the marketing authorisation for the product concerned, where applicable.

iii) Where the marketing authorisation holder and the manufacturer are not the same, appropriate arrangements should be in place, taking into account the principles described in this chapter.

4.3. The contract giver

i) The pharmaceutical quality system of the contract giver should include the control and review of any outsourced activities. The contract giver is ultimately responsible to ensure processes are in place to assure the control of outsourced activities. These processes should incorporate quality risk management principles.

ii) Prior to outsourcing activities, the contract giver is responsible for assessing the legality, suitability and the competence of the contract acceptor to carry out successfully the outsourced activities. The contract giver is also responsible for ensuring by means of the contract that the principles and guidelines of GMP are followed.

iii) The contract giver should provide the contract acceptor with all the information and knowledge necessary to carry out the contracted operations correctly in accordance with regulations in force, and the marketing authorisation for the product concerned. The contract giver should ensure that the contract acceptor is fully aware of any problems associated with the product or the work that might pose a hazard to his premises, equipment, personnel, other materials or other products.

iv) The contract giver should audit, monitor and review the performance of the contract acceptor and the identification and implementation of any needed improvement.

v) The contract giver should be responsible for reviewing and assessing the records and the results related to the outsourced activities. He should also ensure, either by himself, or based on the confirmation of the contract acceptor's qualified person, that all products and materials delivered to him by the contract acceptor have been processed in accordance with GMP and the marketing authorisation.

4.4. The contract acceptor

i) The contract acceptor must be able to carry out satisfactorily the work ordered by the contract giver such as having adequate premises, equipment, knowledge, experience, and competent personnel.

ii) The contract acceptor should ensure that all products, materials and knowledge delivered to him are suitable for their intended purpose.

iii) The contract acceptor should not subcontract to a third party any of the work entrusted to him under the contract without the contract giver's prior evaluation and approval of the arrangements. Arrangements made between the contract acceptor and any third party should ensure that information and knowledge, including those from assessments of the suitability of the third party, are made available in the same way as between the original contract giver and contract acceptor.

iv) The contract acceptor should not make unauthorised changes, outside the terms of the contract, that may adversely affect the quality of the outsourced activities for the contract giver.

v) The contract acceptor should understand that outsourced activities, including contract analysis, may be subject to inspection by the competent authorities.

4.5. The contract

i) A contract should be drawn up between the contract giver and the contract acceptor that specifies their respective responsibilities and communication processes relating to the outsourced activities. Technical aspects of the contract should be drawn up by competent persons suitably knowledgeable in related outsourced activities and GMP. All arrangements for outsourced activities must be in accordance with regulations in force and the marketing authorisation for the product concerned and agreed by both parties.

ii) The contract should describe clearly who undertakes each step of the outsourced activity, e.g. knowledge management, technology transfer, supply chain, subcontracting, quality and

purchasing of materials, testing and releasing materials, undertaking production and quality controls (including in-process controls, sampling and analysis).

iii) All records related to the outsourced activities, e.g. manufacturing, analytical and distribution records, and reference samples, should be kept by, or be available to, the contract giver. Any records relevant to assessing the quality of a product in the event of complaints or a suspected defect or to investigating in the case of a suspected falsified product must be accessible and specified in the relevant procedures of the contract giver.

iv) The contract should permit the contract giver to audit outsourced activities, performed by the contract acceptor or his mutually agreed subcontractors

5. Rules governing complaints and products recall

5.1. Principle

All complaints and other information concerning potentially defective products must be reviewed carefully according to written procedures. A system should be designed to evaluate complaints and initiate a recall from the market, if necessary, promptly and effectively for products known or suspected to be defective.

5.2. Complaints

i) A person should be designated responsible for handling the complaints and deciding the measures to be taken together with sufficient supporting staff to assist him.

ii) There should be written procedures describing the risk evaluation action to be taken, including the need to consider a recall, in the case of a complaint concerning a possible product defect.

iii) Any complaint concerning a product defect should be recorded with all the original details and thoroughly investigated. The person responsible for quality control should normally be involved in the study of such problems.

iv) If a product defect is discovered or suspected in a batch, ingredient or equipment used, consideration should be given to checking other batches in order to determine whether they are also affected. In particular, other batches that may contain reworks of the defective batch should be investigated.

v) All the decisions and measures taken as a result of a complaint should be recorded and referenced to the corresponding batch records.

vi) Complaints records should be reviewed regularly for any indication of specific or recurring problems requiring attention and possibly the recall of marketed products.

vii) Special attention should be given to establishing whether a complaint was caused because of counterfeiting.

viii) The competent authorities should be informed as soon as possible if a manufacturer is considering action following possibly faulty manufacture, product deterioration, detection of counterfeiting or any other serious quality problems with a product

5.3. Recalls

i) A person should be designated as responsible for execution and co-ordination of recalls and should be supported by sufficient staff to handle all the aspects of the recalls with the appropriate degree of urgency. This responsible person should normally be independent of the sales and marketing organisation.

ii) There should be established written procedures, regularly checked and updated when necessary, in order to organise any recall activity.

iii) Recall operations should be capable of being initiated promptly, communicated effectively to customers and at any time.

iv) All Competent Authorities of all countries to which products may have been distributed should be informed promptly if products are intended to be recalled because they are, or are suspected of being defective.

v) The distribution records should be readily available to the person(s) responsible for recalls, and should contain sufficient information on wholesalers and directly supplied customers (with addresses, email addresses, phone or fax numbers inside and outside working hours, batches and amounts delivered), including those for exported products and medical samples.

vi) Recalled products should be identified and stored separately in a secure area while awaiting a decision on their fate.

vii) The progress of the recall process should be recorded and a final report issued, including reconciliation between the delivered and recovered quantities of the products.

viii) The effectiveness of the arrangements for recalls should be evaluated regularly.

6. Rules governing self-inspection

6.1. Principle

Self-inspections should be conducted in order to monitor the implementation and compliance with GMP principles laid down in this guide, and to propose necessary corrective measures.

i) Personnel matters, premises, equipment, documentation, production, quality control, distribution of the vaccines, arrangements for dealing with complaints and recalls, and self-inspection, should be examined at intervals following a pre-arranged programme in order to verify their conformity with the principles of quality assurance.

ii) Self-inspections should be conducted in an independent and detailed way by designated competent person(s) from the company. Independent audits by external experts may also be useful.

iii) All self-inspections should be recorded. Reports should contain all the observations made during the inspections and, where applicable, proposals for corrective measures. Statements on the actions subsequently taken should also be recorded.

CHAPTER 2.3.3.

MINIMUM REQUIREMENTS FOR THE ORGANISATION AND MANAGEMENT OF A VACCINE MANUFACTURING FACILITY

SUMMARY

This chapter sets out the management requirements for the manufacture of veterinary vaccines in accordance with Chapter 1.1.8 Principles of veterinary vaccine production. *Manufacturers should use the chapter as a basis for the elaboration of specific rules adapted to their individual needs. Many of the general principles of laboratory management set out in Chapter 1.1.1* Management of veterinary diagnostic laboratories *are applicable to vaccine production, including accountability, executive management, infrastructure, human resources and compliance.*

There should be sufficient qualified personnel to carry out all the tasks that are the responsibility of the manufacturer. Individual responsibilities should be clearly understood by the individuals and recorded. All personnel should be aware of the principles of Good Manufacturing Practice (GMP) that affect them and receive initial and continuing training, including hygiene instructions, relevant to their needs. Appropriate procedures should be in place for biorisk management, to protect the personnel, to prevent hazardous biological agents from leaving the plant, and to prevent contamination of products within the plant.

Premises and equipment should be located, designed, constructed, adapted and maintained to suit the operations. Their layout and design should aim to minimise the risk of errors and permit effective cleaning and maintenance in order to avoid cross-contamination, build-up of dust or dirt and, in general, any adverse effect on the quality of products.

Good documentation (including electronic records) constitutes an essential part of the quality assurance system and is key to operating in compliance with GMP requirements. The types of documents and electronic media used should be fully defined in the manufacturer's quality management system. The main objective of the system of documentation should be to establish, control, monitor and record all activities that directly or indirectly impact on the quality of products. The quality management system should include sufficient detail to facilitate a common understanding of the requirements, in addition to providing sufficient records of processes and evaluation of observations.

Any outsourced activity should be appropriately defined, agreed and controlled in order to avoid misunderstandings that could result in a product or operation of unsatisfactory quality. Written contracts should cover outsourced activities, products or operations to which they are related, and any connected technical arrangements. All arrangements for the outsourced activities including any proposed changes in technical or other aspects should be in accordance with regulations in force, and the marketing authorisation for the product concerned. Where the marketing authorisation holder and the manufacturer are not the same, appropriate arrangements should be in place to take into account the principles described in this chapter.

All complaints and other information concerning potentially defective products should be reviewed carefully following written procedures. A system should be in place to evaluate complaints and, if necessary, initiate a recall from the market promptly and effectively for products known or suspected to be defective.

Self-inspections should be conducted in order to monitor the implementation and compliance with GMP principles, and to propose necessary corrective measures.

1. Rules for personnel

The establishment and maintenance of a satisfactory system of quality assurance and the correct manufacture of veterinary vaccines relies upon people. For this reason, there must be sufficient qualified personnel to carry out all the tasks that are the responsibility of the manufacturer. Individual responsibilities should be clearly understood by the individuals and recorded. All personnel should be aware of the principles of Good Manufacturing Practices (GMP) that affect them and receive initial and continuing training, including hygiene instructions, relevant to their needs.

1.1. General rules

i) The manufacturer should have an adequate number of personnel with the necessary qualifications and practical experience. The responsibilities placed on any one individual should not be so extensive as to present any risk to quality.

ii) The manufacturer must have an organisation chart. People in responsible positions should have specific duties recorded in written job descriptions and adequate authority to carry out their responsibilities. Their duties may be delegated to designated deputies of a satisfactory qualification level. There should be no gaps or unexplained overlaps in the responsibilities of those personnel concerned with the application of GMP.

1.1.1. Key personnel

i) Key personnel include the head of production, the head of quality control, the head of packaging and distribution, the head of technical services and the person(s) responsible for the batch release. Normally key posts should be occupied by full-time personnel. The heads of production and quality control should be held by different individuals, independent from each other. In large organisations, it may be necessary to delegate some of the functions.

1.1.2. Training

i) The manufacturer should provide training for all the personnel whose duties take them into production areas or into control laboratories (including the technical, maintenance and cleaning personnel), and for other personnel whose activities could affect the quality of the product.

ii) Besides the basic training on the theory and practice of GMP, newly recruited personnel should receive training appropriate to the duties assigned to them. Continuing training should also be given, and its practical effectiveness should be periodically assessed. Training programmes should be available, approved by a qualified person. Training records should be kept.

iii) Personnel working in areas where contamination is a hazard, e.g. clean areas or areas where highly active, toxic, infectious or sensitising materials are handled, should be given specific training (see Section 2.4 *Specific requirements for vaccine production*).

iv) Visitors or untrained personnel should, preferably, not be taken into the production and quality control areas. If this is unavoidable, they should be given information in advance, particularly about personal hygiene and the prescribed protective clothing. They should be closely supervised.

v) The concept of quality assurance and all the measures capable of improving its understanding and implementation should be fully discussed during the training sessions.

1.1.3. Personal hygiene

i) Detailed hygiene programmes should be established and adapted to the different needs within the factory. They should include procedures relating to the health, hygiene practices and clothing of personnel. These procedures should be understood and followed in a very strict way by every person whose duties take him into the production and control areas. Hygiene programmes should be promoted by management and widely discussed during training sessions.

ii) All personnel should receive a medical examination upon recruitment. It must be the manufacturer's responsibility that there are instructions ensuring that health conditions that can be of relevance to the quality of products come to the manufacturer's knowledge. After the first medical examination, examinations should be carried out when necessary for the work and personal health.

iii) Steps should be taken to ensure as far as is practicable that no person affected by an infectious disease or having open lesions on the exposed surface of the body is engaged in the manufacture of vaccines.

iv) Every person entering the manufacturing areas should wear protective garments appropriate to the operations to be carried out.

v) Eating, drinking, chewing or smoking, or the storage of food, drink, smoking materials or personal medication in the production and storage areas should be prohibited. In general, any unhygienic practice within the manufacturing areas or in any other area where the product might be adversely affected should be forbidden.

vi) Direct contact should be avoided between the operator's hands and the exposed product as well as with any part of the equipment that comes into contact with the products.

vii) Personnel should be instructed to use the hand-washing facilities.

viii) Any specific requirements for the manufacture of aseptic or sterile preparations related to production are covered in 2.4 *Specific requirements for vaccine production*.

1.2. Specific rules for personnel involved in the manufacture of vaccines

i) All personnel (including those concerned with cleaning and maintenance) employed in areas where immunological products are manufactured should be given training in and information on hygiene and microbiology. They should receive additional training specific to the products with which they work.

ii) Responsible personnel should be formally trained in some or all of the required fields.

iii) Personnel should be protected against possible infection with the biological agents used in manufacture. In the case of biological agents known to cause disease in humans, adequate measures should be taken to prevent infection of personnel working with the agent or with experimental animals.

iv) Where relevant, the personnel should be vaccinated and subject to medical examination.

v) Adequate measures should be taken to prevent biological agents being taken outside the manufacturing plant by personnel acting as a carrier. Dependent on the type of biological agent, such measures may include complete change of clothes and compulsory showering before leaving the production area.

vi) For immunological products, the risk of contamination or cross-contamination by personnel is particularly important.

vii) Prevention of contamination by personnel should be achieved by a set of measures and procedures to ensure that appropriate protective clothing is used during the different stages of the production process.

viii) Prevention of cross-contamination by personnel involved in production should be achieved by a set of measures and procedures to ensure that they do not pass from one area to another unless they have taken appropriate measures to eliminate the risk of contamination. In the course of a working day, personnel should not pass from areas where contamination with live micro-organisms is likely or where animals are housed to premises where other products or organisms are handled. If such passage is unavoidable, clearly defined decontamination procedures, including change of clothing and shoes, and, where necessary, showering, should be followed by staff involved in any such production.

ix) Personnel entering a contained area where organisms had not been handled in open circuit operations in the previous 12 hours to check on cultures in sealed, surface decontaminated flasks would not be regarded as being at risk of contamination, unless the organism involved was an exotic.

2. Requirements for premises and equipment

Premises and equipment must be located, designed, constructed, adapted and maintained to suit the operations to be carried out. Their layout and design must aim to minimise the risk of errors and permit effective cleaning and maintenance in order to avoid cross-contamination, build-up of dust or dirt and, in general, any adverse effect on the quality of products.

Premises and equipment used for critical operations must be qualified[1].

Added requirements for premises and equipment used in aseptic preparations are given in 2.4 *Specific requirements for vaccine production.*

2.1. General

i) Premises should be situated in an environment which, when considered together with measures to protect the manufacture, presents minimal risk of causing contamination of materials or products. Research and development activities associated with organisms not authorised to be handled in the premises must be carried out in buildings completely separated from the manufacturing facility.

ii) Premises should be carefully maintained, ensuring that repair and maintenance operations do not present any hazard to the quality of products. They should be cleaned and, where applicable, disinfected according to detailed written procedures.

iii) Lighting, temperature, humidity and ventilation should be appropriate and such that they do not adversely affect, directly or indirectly, either the medicinal products during their manufacture and storage, or the accurate functioning of equipment.

iv) Premises should be designed and equipped so as to afford maximum protection against the entry of insects or other animals.

v) Steps should be taken in order to prevent the entry of unauthorised people. Production, storage and quality control areas should not be used as a right of way by personnel who do not work in them.

2.2. Storage areas

i) Storage areas should be of sufficient capacity to allow orderly storage of the various categories of materials and products: starting and packaging materials, intermediate, bulk and finished products, products in quarantine, released, rejected, returned or recalled.

ii) Storage areas should be designed or adapted to ensure good storage conditions. In particular, they should be clean and dry and maintained within acceptable temperature limits. Where special storage conditions are required (e.g. temperature, humidity) these should be validated, checked and monitored.

iii) Receiving and dispatch bays should protect materials and products from the weather. Reception areas should be designed and equipped to allow containers of incoming materials to be cleaned where necessary before storage.

1 This qualification may be done according to the rules laid down in the PIC/S (see References).

iv) Where quarantine status is ensured by storage in separate areas, these areas must be clearly marked and their access restricted to authorised personnel. Any system replacing the physical quarantine should give equivalent security.

v) There should normally be a separate sampling area for starting materials. If sampling is performed in the storage area, it should be conducted in such a way as to prevent contamination or cross-contamination.

vi) Segregated areas should be provided for the storage of rejected, recalled or returned materials or products.

vii) Highly active materials or products should be stored in safe and secure areas.

viii) Printed packaging materials are considered critical to the conformity of the vaccine and special attention should be paid to the safe and secure storage of these materials.

2.3. Production premises – general requirements

i) Premises should preferably be laid out in such a way as to allow the production to take place in areas connected in a logical order corresponding to the sequence of the operations and to the requisite cleanliness levels.

ii) The adequacy of the working and in-process storage space should permit the orderly and logical positioning of equipment and materials so as to minimise the risk of confusion between different medicinal products or their components, to avoid cross-contamination and to minimise the risk of omission or wrong application of any of the manufacturing or control steps.

iii) Where starting and primary packaging materials, intermediate or bulk products are exposed to the environment, interior surfaces (walls, floors and ceilings) should be smooth, free from cracks and open joints, and should not shed particulate matter and should permit easy and effective cleaning and, if necessary, disinfection.

iv) Pipework, light fittings, ventilation points and other services should be designed and sited to avoid the creation of recesses that are difficult to clean. As far as possible, for maintenance purposes, they should be accessible from outside the manufacturing areas.

v) Drains should be of adequate size, and have trapped gullies. Open channels should be avoided where possible, but if necessary, they should be shallow to facilitate cleaning and disinfection.

vi) Production areas should be effectively ventilated, with air control facilities (including temperature and, where necessary, humidity and filtration) appropriate both to the products handled, to the operations undertaken within them and to the external environment.

vii) Weighing of starting materials usually should be carried out in a separate weighing room designed for that use.

viii) In cases where dust is generated (e.g. during sampling, weighing, mixing and processing operations, packaging of dry products), specific provisions should be taken to avoid cross-contamination and facilitate cleaning.

ix) Premises for the packaging of vaccines should be specifically designed and laid out so as to avoid mix-ups or cross-contamination.

x) Production areas should be well lit, particularly where visual on-line controls are carried out.

xi) In-process controls may be carried out within the production area provided they do not carry any risk for the production.

2.3.1. Ancillary areas

i) Rest and refreshment rooms should be separate from other areas.

ii) Facilities for changing clothes and for washing and toilet purposes should be easily accessible and appropriate for the number of users. Toilets should not directly communicate with production or storage areas.

iii) Maintenance workshops should as far as possible be separated from production areas. Whenever parts and tools are stored in the production area, they should be kept in rooms or lockers reserved for that use.

2.3.2. Quality control areas

i) Normally, quality control laboratories should be separated from production areas. This is particularly important for laboratories for the control of biologicals, microbiologicals and radioisotopes, which should also be separated from each other.

ii) Control laboratories should be designed to suit the operations to be carried out in them. Sufficient space should be given to avoid mix-ups and cross-contamination. There should be adequate suitable storage space for samples and records.

iii) Separate rooms may be necessary to protect sensitive instruments from vibration, electrical interference, humidity, etc.

iv) Special requirements are needed in laboratories handling particular substances, such as biological or radioactive samples.

v) Animal houses should be well isolated from other areas, with separate entrance (animal access) and air handling facilities.

2.4. Specific requirements for vaccine production

2.4.1. Production areas

i) Premises should be designed in such a way as to control both the risk to the product and to the environment. This can be achieved by the use of containment, clean, clean or contained or controlled areas[2].

ii) Live biological agents should be handled in contained areas. The level of containment should depend on the pathogenicity of the micro-organism and whether it has been classified as exotic.

iii) Inactivated biological agents should be handled in clean areas. Clean areas should also be used when handling non-infected cells isolated from multicellular organisms and, in some cases, filtration-sterilised media.

iv) Open circuit operations involving products or components not subsequently sterilised should be carried out within a laminar air flow work station according to the rules for aseptic preparation.

v) Other operations where live biological agents are handled (quality control, research and diagnostic services, etc.) should be appropriately contained and separated if production operations are carried out in the same building. The level of containment should depend on the pathogenicity of the biological agent and whether they have been classified as exotic. Whenever diagnostic activities are carried out, there is the risk of introducing highly pathogenic organisms. Therefore, the level of containment should be adequate to cope with all such risks. Containment may also be required if quality control or other activities are carried out in buildings in close proximity to those used for production.

vi) Containment premises should be easily disinfected and should have the following characteristics:

a) the absence of direct venting to the outside;

2 Guidance on the qualification of the clean areas is given in ISO 14644 and described in the PIC/S GMP Guide (see References).

b) a ventilation system with air at negative pressure. Air should be extracted through HEPA (high-efficiency particulate air) filters and not be re-circulated except to the same area, and provided further HEPA filtration is used (normally this condition would be met by routing the re-circulated air through the normal supply HEPAs for that area). However, recycling of air between areas may be permissible provided that it passes through two exhaust HEPAs, the first of which is continuously monitored for integrity, and there are adequate measures for safe venting of exhaust air should this filter fail;

c) air from manufacturing areas used for the handling of exotic organisms should be vented through two sets of HEPA filters in series, and that from production areas not re-circulated;

d) a system for the collection and disinfection of liquid effluents (see Section 2.4.4 *Disinfection – waste disposal*);

e) changing rooms designed and used as air locks, and equipped with washing and showering facilities if appropriate. Air pressure differentials should be such that there is no flow of air between the work area and the external environment or risk of contamination of outer clothing worn outside the area;

f) an air lock system for the passage of equipment, which is constructed so that there is no flow of contaminated air between the work area and the external environment or risk of contamination of equipment within the lock. The air lock should be of a size that enables the effective surface decontamination of materials being passed through it. Consideration should be given to having a timing device on the door interlock to allow sufficient time for the decontamination process to be effective.

g) in many instances, a barrier double-door autoclave for the secure removal of waste materials and introduction of sterile items.

vii) Water treatment plants and distribution systems should be designed, constructed and maintained so as to ensure a reliable source of water of an appropriate quality. They should not be operated beyond their designed capacity. Water for injections should be produced, stored and distributed in a manner that prevents microbial growth, for example by constant circulation at a temperature above 70°C.

viii) Equipment passes and changing rooms should have an interlock mechanism or other appropriate system to prevent the opening of more than one door at a time. Changing rooms should be supplied with air filtered to the same standard as that for the work area, and equipped with air extraction facilities to produce an adequate air circulation independent of that of the work area. Equipment passes should normally be ventilated in the same way, but unventilated passes, or those equipped with supply air only, may be acceptable.

ix) Production operations such as cell maintenance, media preparation, virus culture, etc., likely to cause contamination should be performed in separate areas. Animals and animal products should be handled with appropriate precautions.

x) Production areas where biological agents particularly resistant to disinfection (e.g. spore forming bacteria) are handled should be separated and dedicated to that particular purpose until the biological agents have been inactivated.

xi) With the exception of blending and subsequent filling operations (for example with multi-valent vaccines), one biological agent only should be handled at a time within an area.

xii) Production areas should be designed to permit disinfection between campaigns, using validated methods.

xiii) Production of biological agents may take place in controlled areas provided it is carried out in totally enclosed and heat-sterilised equipment, all connections being also heat sterilised after making and before breaking. It may be acceptable for connections to be made under local laminar air flow provided these are few in number and proper aseptic techniques are used and there is no risk of leakage. The sterilisation parameters used before breaking the connections must be validated for the organisms being used. Different products may be placed in different biogenerators (fermenters), within the same area, provided that there is

no risk of accidental cross-contamination. However, organisms generally subject to special requirements for containment should be in areas dedicated to such products.

xiv) Access to manufacturing areas should be restricted to authorised personnel. Clear and concise written procedures should be posted as appropriate.

xv) The manufacturing site and buildings should be described in sufficient detail (by means of plans and written explanations) so that the designation and conditions of use of all the rooms are correctly identified as well as the biological agents that are handled in them. The flow of people and product should also be clearly marked.

xvi) The activities carried out in the vicinity of the site should also be indicated.

xvii) Plans of contained or clean area premises should describe the ventilation system indicating inlets and outlets, filters and their specifications, the number of air changes per hour, and pressure gradients. They should indicate which pressure gradients are monitored by pressure indicator.

2.4.2. Animals and animal houses

i) Animal houses should be separated from the other production premises and suitably designed.

ii) The sanitary status of the animals used for production should be defined, monitored, and recorded. Some animals should be handled as defined in specific monographs (e.g. specific pathogen free [SPF] flocks).

iii) Animals, biological agents, and tests carried out should be the subject of an identification system so as to prevent any risk of confusion and to control all possible hazards.

iv) Animal houses where animals intended or used for production are accommodated, should be provided with the appropriate containment or clean area measures, and should be separate from other animal accommodation.

v) Animal houses where animals used for quality control, involving the use of pathogenic biological agents, are accommodated, should be adequately contained.

vi) The animal species accommodated in the animal houses or otherwise on the site should be identified.

2.4.3. Equipment

i) The equipment used should be designed and constructed so that it meets the particular requirements for the manufacture of each product.

ii) Before being put into operation the equipment should be qualified and validated and subsequently be regularly maintained and validated.

iii) Where appropriate, the equipment should ensure satisfactory primary containment of the biological agents.

iv) Where appropriate, the equipment should be designed and constructed as to allow easy and effective decontamination or sterilisation.

v) Closed equipment used for the primary containment of the biological agents should be designed and constructed as to prevent any leakage or the formation of droplets and aerosols.

vi) Inlets and outlets for gases should be protected so as to achieve adequate containment, e.g. by the use of sterilising hydrophobic filters.

vii) The introduction or removal of material should take place using a sterilisable closed system, or possibly in an appropriate laminar air flow.

viii) Equipment where necessary should be properly sterilised before use, preferably by pressurised dry steam. Other methods can be accepted if steam sterilisation cannot be used because of the nature of the equipment. It is important not to overlook such individual items as bench centrifuges and water baths.

ix) Equipment used for purification, separation or concentration should be sterilised or disinfected at least between use for different products. The effect of the sterilisation methods on the effectiveness and validity of the equipment should be studied in order to determine the life span of the equipment.

x) All sterilisation procedures should be validated.

xi) Equipment should be designed so as to prevent any mix-up between different organisms or products. Pipes, valves and filters should be identified as to their function.

xii) Separate incubators should be used for infected and non-infected containers and also generally for different organisms or cells. Incubators containing more than one organism or cell type will only be acceptable if adequate steps are taken to seal, surface decontaminate and segregate the containers.

xiii) Culture vessels, etc., should be individually labelled. The cleaning and disinfection of the items can be particularly difficult and should receive special attention.

xiv) Equipment used for the storage of biological agents or products should be designed and used in such a manner as to prevent any possible mix-up. All stored items should be clearly and unambiguously labelled and in leak-proof containers. Items such as cells and organisms seed stock should be stored in dedicated equipment.

xv) Relevant equipment, such as that requiring temperature control, should be fitted with recording or alarm systems.

xvi) To avoid breakdowns, a system of preventive maintenance, together with trend analysis of recorded data, should be implemented.

xvii) The loading of freeze dryers requires an appropriate clean or contained area. Unloading freeze dryers contaminate the immediate environment. Therefore, for single-ended freeze dryers, the clean room should be decontaminated before a further manufacturing batch is introduced into the area, unless this contains the same organisms, and double door freeze dryers should be sterilised after each cycle unless opened in a clean area.

xviii) Sterilisation of freeze dryers should be done before use, preferably by pressurised dry steam. In case of campaign working, they should at least be sterilised after each campaign.

2.4.4. Disinfection – waste disposal

i) Disinfection or wastes and effluents disposal may be particularly important in the case of manufacture of immunological products. Careful consideration should therefore be given to procedures and equipment aiming at avoiding environmental contamination as well as to their validation or qualification.

3. Rules governing documentation

Documentation relating to the premises should be readily available in a **Site Master File**.

3.1. Principle

Good documentation constitutes an essential part of the quality assurance system and is key to operating in compliance with GMP requirements. The various types of documents and media used should be fully defined in the manufacturer's quality management system. Documentation may exist in a variety of forms, including paper-based, electronic or photographic media. The main objective of the system of documentation used must be to establish, control, monitor and record all activities that directly or indirectly impact on all aspects of the quality of products. The quality management system should include sufficient instructional detail to facilitate a common understanding of the requirements, in addition to providing for sufficient recording of the various processes and evaluation of any observations, so that on-going application of the requirements may be demonstrated.

There are two primary types of documentation used to manage and record GMP compliance: instructions (directions, requirements) and records or reports.

Suitable controls should be implemented to ensure the accuracy, integrity, availability and legibility of documents. Instruction documents should be free from errors and available in writing. This includes electronic records from which data may be rendered in a human readable form.

3.2. Required documentation

i) **Site Master File:** a document describing the GMP related activities of the manufacturer.

3.2.1. Instructions

i) **Specifications** describe in detail the requirements with which the products or materials used or obtained during manufacture have to conform. They serve as a basis for quality evaluation.

ii) **Manufacturing composition, processing, packaging and testing instructions** provide detail all the starting materials, equipment and computerised systems (if any) to be used and specify all processing, packaging, sampling and testing instructions. In-process controls and process analytical technologies to be employed should be specified where relevant, together with acceptance criteria.

iii) **Protocols** give instructions for performing and recording certain discreet operations.

iv) **Technical agreements** are agreed between contract givers and acceptors for outsourced activities.

3.2.2. Records or Reports

i) **Records** provide evidence of various actions taken to demonstrate compliance with instructions, including activities, events, investigations, and in the case of manufactured batches a history of each batch of product, from initiation of manufacture to final distribution. Records include the raw data that is used to generate other records. For electronic records regulated users should define which data are to be used as raw data. At least, all data on which quality decisions are based should be defined as raw data

ii) **Certificates of analysis** provide a summary of testing results on samples of products or materials together with the evaluation for compliance to a stated specification.

iii) **Reports** document the conduct of particular exercises, projects or investigations, together with results, conclusions and recommendations.

3.3. Generation and control of documentation

i) All types of document should be defined and adhered to. The requirements apply equally to all forms of document media types. Complex systems need to be understood, well documented, validated, and adequate controls should be in place. Many documents (instructions or records) may exist in hybrid forms, i.e. some elements as electronic and others as paper based. Relationships and control measures for master documents, official copies, data handling and records need to be stated for both hybrid and homogenous systems. Appropriate controls for electronic documents such as templates, forms, and master documents should be implemented. Appropriate controls should be in place to ensure the integrity and authenticity of the record throughout the retention period.

ii) Documents should be designed, prepared, reviewed, and distributed with care. They should comply with the relevant parts of product specification files, manufacturing and marketing authorisation dossiers, as appropriate. The reproduction of working documents from master documents should not allow any error to be introduced through the reproduction process.

iii) Documents containing instructions should be approved, signed and dated by appropriate and authorised persons. Documents should have unambiguous contents and be uniquely identifiable. The effective date should be defined.

iv) Documents containing instructions should be laid out in an orderly fashion and be easy to check. The style and language of documents should fit with their intended use. Standard Operating Procedures (SOPs), work instructions and methods should be written in an imperative mandatory style.

v) Documents within the quality management system should be regularly reviewed and kept up-to-date.

vi) Documents should not be hand-written; although, where documents require the entry of data, sufficient space should be provided for such entries.

3.4. Good documentation practices

i) Handwritten entries should be made in clear, legible, indelible way.

ii) Records should be made or completed at the time each action is taken and in such a way that all significant activities concerning the manufacture of vaccines are traceable.

iii) Any alteration made to the entry on a document should be signed and dated; the alteration should permit the reading of the original information. Where appropriate, the reason for the alteration should be recorded.

3.5. Retention of documents

i) It should be clearly defined which record is related to each manufacturing activity and where this record is located. Secure controls must be in place to ensure the integrity of the record throughout the retention period and validated where appropriate.

ii) Specific requirements apply to batch documentation that must be kept for 1 year after expiry of the batch to which it relates or at least 5 years after certification of the batch by the authorised person, whichever is the longer. For investigational vaccines, the batch documentation must be kept for at least 5 years after the completion or formal discontinuation of the last clinical trial in which the batch was used.

For other types of documentation, the retention period will depend on the business activity that the documentation supports. Critical documentation, including raw data (for example relating to validation or stability), which supports information in the marketing authorisation should be retained whilst the authorisation remains in force. It may be considered acceptable to retire certain documentation (e.g. raw data supporting validation reports or stability reports) where the data has been superseded by a full set of new data.

More information and details can be found on documentation within the PIC/S GMP guide (PIC/S, PE 009-11 [Part I], see References).

4. Rules governing outsourced activities

4.1. Principle

Any activity that is outsourced should be appropriately defined, agreed and controlled in order to avoid misunderstandings that could result in a product or operation of unsatisfactory quality.

4.2. General

i) There should be a written contract covering the outsourced activities, the products or operations to which they are related, and any technical arrangements made in connection with it.

ii) All arrangements for the outsourced activities including any proposed changes in technical or other arrangements should be in accordance with regulations in force, and the marketing authorisation for the product concerned, where applicable.

iii) Where the marketing authorisation holder and the manufacturer are not the same, appropriate arrangements should be in place, taking into account the principles described in this chapter.

4.3. The contract giver

i) The pharmaceutical quality system of the contract giver should include the control and review of any outsourced activities. The contract giver is ultimately responsible to ensure processes are in place to assure the control of outsourced activities. These processes should incorporate quality risk management principles.

ii) Prior to outsourcing activities, the contract giver is responsible for assessing the legality, suitability and the competence of the contract acceptor to carry out successfully the outsourced activities. The contract giver is also responsible for ensuring by means of the contract that the principles and guidelines of GMP are followed.

iii) The contract giver should provide the contract acceptor with all the information and knowledge necessary to carry out the contracted operations correctly in accordance with regulations in force, and the marketing authorisation for the product concerned. The contract giver should ensure that the contract acceptor is fully aware of any problems associated with the product or the work that might pose a hazard to his premises, equipment, personnel, other materials or other products.

iv) The contract giver should audit, monitor and review the performance of the contract acceptor and the identification and implementation of any needed improvement.

v) The contract giver should be responsible for reviewing and assessing the records and the results related to the outsourced activities. He should also ensure, either by himself, or based on the confirmation of the contract acceptor's qualified person, that all products and materials delivered to him by the contract acceptor have been processed in accordance with GMP and the marketing authorisation.

4.4. The contract acceptor

i) The contract acceptor must be able to carry out satisfactorily the work ordered by the contract giver such as having adequate premises, equipment, knowledge, experience, and competent personnel.

ii) The contract acceptor should ensure that all products, materials and knowledge delivered to him are suitable for their intended purpose.

iii) The contract acceptor should not subcontract to a third party any of the work entrusted to him under the contract without the contract giver's prior evaluation and approval of the arrangements. Arrangements made between the contract acceptor and any third party should ensure that information and knowledge, including those from assessments of the suitability of the third party, are made available in the same way as between the original contract giver and contract acceptor.

iv) The contract acceptor should not make unauthorised changes, outside the terms of the contract, that may adversely affect the quality of the outsourced activities for the contract giver.

v) The contract acceptor should understand that outsourced activities, including contract analysis, may be subject to inspection by the competent authorities.

4.5. The contract

i) A contract should be drawn up between the contract giver and the contract acceptor that specifies their respective responsibilities and communication processes relating to the outsourced activities. Technical aspects of the contract should be drawn up by competent persons suitably knowledgeable in related outsourced activities and GMP. All arrangements for outsourced activities must be in accordance with regulations in force and the marketing authorisation for the product concerned and agreed by both parties.

ii) The contract should describe clearly who undertakes each step of the outsourced activity, e.g. knowledge management, technology transfer, supply chain, subcontracting, quality and

purchasing of materials, testing and releasing materials, undertaking production and quality controls (including in-process controls, sampling and analysis).

iii) All records related to the outsourced activities, e.g. manufacturing, analytical and distribution records, and reference samples, should be kept by, or be available to, the contract giver. Any records relevant to assessing the quality of a product in the event of complaints or a suspected defect or to investigating in the case of a suspected falsified product must be accessible and specified in the relevant procedures of the contract giver.

iv) The contract should permit the contract giver to audit outsourced activities, performed by the contract acceptor or his mutually agreed subcontractors

5. Rules governing complaints and products recall

5.1. Principle

All complaints and other information concerning potentially defective products must be reviewed carefully according to written procedures. A system should be designed to evaluate complaints and initiate a recall from the market, if necessary, promptly and effectively for products known or suspected to be defective.

5.2. Complaints

i) A person should be designated responsible for handling the complaints and deciding the measures to be taken together with sufficient supporting staff to assist him.

ii) There should be written procedures describing the risk evaluation action to be taken, including the need to consider a recall, in the case of a complaint concerning a possible product defect.

iii) Any complaint concerning a product defect should be recorded with all the original details and thoroughly investigated. The person responsible for quality control should normally be involved in the study of such problems.

iv) If a product defect is discovered or suspected in a batch, ingredient or equipment used, consideration should be given to checking other batches in order to determine whether they are also affected. In particular, other batches that may contain reworks of the defective batch should be investigated.

v) All the decisions and measures taken as a result of a complaint should be recorded and referenced to the corresponding batch records.

vi) Complaints records should be reviewed regularly for any indication of specific or recurring problems requiring attention and possibly the recall of marketed products.

vii) Special attention should be given to establishing whether a complaint was caused because of counterfeiting.

viii) The competent authorities should be informed as soon as possible if a manufacturer is considering action following possibly faulty manufacture, product deterioration, detection of counterfeiting or any other serious quality problems with a product

5.3. Recalls

i) A person should be designated as responsible for execution and co-ordination of recalls and should be supported by sufficient staff to handle all the aspects of the recalls with the appropriate degree of urgency. This responsible person should normally be independent of the sales and marketing organisation.

ii) There should be established written procedures, regularly checked and updated when necessary, in order to organise any recall activity.

iii) Recall operations should be capable of being initiated promptly, communicated effectively to customers and at any time.

iv) All Competent Authorities of all countries to which products may have been distributed should be informed promptly if products are intended to be recalled because they are, or are suspected of being defective.

v) The distribution records should be readily available to the person(s) responsible for recalls, and should contain sufficient information on wholesalers and directly supplied customers (with addresses, email addresses, phone or fax numbers inside and outside working hours, batches and amounts delivered), including those for exported products and medical samples.

vi) Recalled products should be identified and stored separately in a secure area while awaiting a decision on their fate.

vii) The progress of the recall process should be recorded and a final report issued, including reconciliation between the delivered and recovered quantities of the products.

viii) The effectiveness of the arrangements for recalls should be evaluated regularly.

6. Rules governing self-inspection

6.1. Principle

Self-inspections should be conducted in order to monitor the implementation and compliance with GMP principles laid down in this guide, and to propose necessary corrective measures.

i) Personnel matters, premises, equipment, documentation, production, quality control, distribution of the vaccines, arrangements for dealing with complaints and recalls, and self-inspection, should be examined at intervals following a pre-arranged programme in order to verify their conformity with the principles of quality assurance.

ii) Self-inspections should be conducted in an independent and detailed way by designated competent person(s) from the company. Independent audits by external experts may also be useful.

iii) All self-inspections should be recorded. Reports should contain all the observations made during the inspections and, where applicable, proposals for corrective measures. Statements on the actions subsequently taken should also be recorded.

CHAPTER 2.3.4.

MINIMUM REQUIREMENTS FOR THE PRODUCTION AND QUALITY CONTROL OF VACCINES

SUMMARY

This chapter provides requirements for the manufacture and quality control of veterinary vaccines in accordance with Chapter 1.1.8 Principles of veterinary vaccine production. *Manufacturers should use the recommendations as a basis for the elaboration of specific rules adapted to their individual needs.*

Production operations should follow clearly defined procedures that comply with the principles elaborated in this chapter, in order to obtain products of the requisite quality in accordance with the marketing authorisations. The manufacture of immunological veterinary medicinal products has special characteristics that should be considered when implementing and assessing the quality assurance system.

Due to the large number of animal species and related pathogenic agents, the variety of products manufactured is very wide and the volume of manufacture is often low. The products should be protected against organic or inorganic contamination and cross-contamination. The environment must also be protected, especially when using pathogenic or exotic biological agents, and personnel must be protected from biological agents pathogenic to humans. The role of the quality assurance system is therefore of paramount importance.

Quality control is concerned with sampling, specifications and testing as well as the organisation, documentation and release procedures to ensure that the necessary and relevant tests are carried out, and that materials are not released for use, nor products released for sale or supply, until their quality has been judged satisfactory. Quality control is not confined to laboratory operations, but must be involved in all decisions that may concern the quality of the product. The independence of quality control from production is considered fundamental to the satisfactory operation of quality control. That is, production or management personnel should not coerce or force quality assurance personnel to depart from approved specifications or procedures.

1. General requirements for vaccine production

1.1. Principle

Production operations must follow clearly defined approved current procedures; they must comply with the following principles in order to obtain products of the requisite quality and be in accordance with the relevant manufacturing and marketing authorisations.

The manufacture of immunological veterinary medicinal products has special characteristics that should be taken into consideration when implementing and assessing the quality assurance system.

Due to the large number of animal species and related pathogenic agents, the variety of products manufactured is very wide and the volume of manufacture is often low. Hence, work on a campaign basis is common, manufacturing a series of batches of the same product in sequence in a given period of time followed by an appropriate cleaning procedure. Moreover, because of the very nature of this manufacture (cultivation steps, lack of terminal sterilisation), the products must be particularly well protected against organic or inorganic contamination and cross-contamination. The environment also

must be protected, especially when the manufacture involves the use of pathogenic or exotic biological agents, and the worker must be particularly well protected when the manufacture involves the use of biological agents pathogenic to humans.

These factors, together with the inherent variability of immunological products and the destructive nature of final product quality control tests so that they can provide only an estimate of quality for the entire batch mean that the role of the quality assurance system is of the utmost importance.

1.2. General

i) Production should be performed and supervised by competent people. Workers must understand the theory behind and practice of their work to the extent that they can predict and prevent problems within the scope of their responsibility.

ii) All handling of materials and products, such as receipt and quarantine, sampling, storage, labelling, dispensing, processing, packaging and distribution should be done in accordance with approved written procedures or instructions and adequately documented.

iii) All incoming materials should be evaluated to assess the quality impact on manufacturing. Appropriate action should be taken when materials are determined to be compromised. Materials should be labelled with the prescribed specifications.

iv) Incoming materials and finished products should be physically or administratively quarantined immediately after receipt or processing, until they have been released for use or distribution.

v) Intermediate and bulk products purchased as such should be handled on receipt as though they were starting materials.

vi) All materials and products should be stored under the appropriate conditions as established by the manufacturer and in an orderly fashion to permit batch segregation and stock rotation according to life expectancy.

vii) Checks on yields, and reconciliation of quantities, should be carried out as necessary to ensure that there are no discrepancies outside acceptable limits.

viii) Operations on different products should not be carried out simultaneously or consecutively in the same room unless there is negligible risk of mix-up or cross-contamination.

ix) At every stage of processing, products and materials should be protected from microbial and other contamination. A method of measuring bioburden within the production facility should be established.

x) When working with dry materials and products, special precautions should be taken to prevent the generation and dissemination of dust particulates. This applies particularly to the handling of highly active or sensitising materials.

xi) At all times during processing, all materials, bulk containers, critical items of equipment and where appropriate rooms used should be labelled or otherwise identified with an indication of the product or material being processed, its strength or concentration (where applicable) and batch number. Where applicable, this indication should also mention the stage of production.

xii) Labels applied to containers, equipment or premises should be clear, unambiguous and in the company's approved format. It is often helpful in addition to the wording on the labels to use colours to indicate status (for example, quarantined, accepted, rejected, clean, etc.).

xiii) Checks should be carried out to ensure that pipelines and other pieces of equipment used for the transportation of products from one area to another are connected in a correct manner.

xiv) Any deviation from instructions or procedures should be avoided as far as possible. If a deviation occurs, it should be approved in writing by a competent authorised person, with the involvement of the quality control department as appropriate to evaluate the effect on product quality and the shelf

life of the product. Deviations from documents approved by regulatory bodies should be reported to them for written approval prior to release of product.

xv) Access to production premises should be restricted to authorised personnel.

xvi) Normally, the production of other products should be avoided in areas destined for the production of vaccines, and should not use the same equipment.

1.3. Prevention of cross-contamination in production

i) Contamination of a starting material or of a product by another material or product should be avoided. This risk of accidental cross-contamination arises from the uncontrolled release of dust, gases, vapours, sprays or organisms from materials and products in process, from residues on equipment, residues from excipients or packaging and from operators' clothing, skin and respiratory tract. The significance of this risk varies with the type of contaminant and of product being contaminated. Amongst the most hazardous contaminants are biological preparations containing living organisms.

ii) Cross-contamination should be avoided by appropriate technical or organisational measures, for example:

a) production in segregated areas or by campaign (separation in time) followed by appropriate cleaning;

b) providing appropriate air-locks and air extraction;

c) minimising the risk of contamination caused by recirculation or re-entry of untreated or insufficiently treated air; routine testing of air;

d) keeping protective clothing inside areas where products with special risk of cross-contamination are processed;

e) using cleaning and decontamination procedures of known effectiveness, as ineffective cleaning of equipment is a common source of cross-contamination;

f) using "closed systems" of production;

g) testing for residues and contamination, and use of cleaning status labels on equipment.

iii) Measures to prevent cross-contamination and their effectiveness should be checked periodically according to set procedures.

1.4. Starting materials

i) The suitability of starting materials should be clearly defined in written specifications. These should include details of the supplier, catalogue or part number, the method of manufacture, the geographical origin and the animal species from which the materials are derived. The controls to be applied to starting materials must be included. Microbiological controls are particularly important.

ii) The results of tests on starting materials must comply with the specifications. Where the tests take a long time (e.g. eggs from SPF flocks) it may be necessary to process starting materials before the results of analytical controls are available. In such cases, the release of a finished product is conditional upon satisfactory results of the tests on starting materials. While vendors' certificates of analysis are useful and may be an acceptance requirement, they should not replace testing by the manufacturer when those test results are critical to acceptance.

iii) Special attention should be paid to knowledge of the supplier's quality assurance system in assessing the suitability of a source and the extent of quality control testing required.

iv) Heat is the preferred method for sterilising starting materials and some equipment. If necessary, other validated methods, such as irradiation, may be used. Steam heat should use live steam at no less than 120°C for not less than 30 minutes. Dry heat should be at no less than 160°C for not less than 1 hour.

1.5. Media

i) The ability of media to support the desired growth and effectiveness should be properly validated in advance.

ii) Media should preferably be sterilised *in situ* or in line. Steam heat under pressure is the preferred method. Gases, media, acids, alkalis, de-foaming agents and other materials introduced into bioreactors should themselves be sterile.

1.6. Seed lot and cell bank system

Where appropriate, the standards for seed lot and cell bank systems in relation to specific-disease chapters in the *Terrestrial Manual* should be consulted.

i) In order to prevent the unwanted drift of properties that ensue from repeated subcultures or multiple generations, the production of immunological veterinary medicinal products obtained by microbial, cell or tissue culture, or propagation in embryos and animals, should be based on a system of limited and controlled passages of seed lots or cell banks with a specified maximum.

ii) The number of generations (doublings, passages) between the seed lot or cell bank and the finished product should be consistent with the relevant dossier regulatory approval.

iii) Seed lots and cell banks should be adequately characterised and tested for contaminants (freedom from extraneous bacteria, fungi, mycoplasma, and viruses) and to ensure identity, purity, safety and efficacy when required by regulators. Cell banks should also be tested for karyology at baseline and maximum passage. Regulatory bodies may require confirmatory testing. Acceptance criteria for new seed lots should be established. Seed lots and cell banks should be established, stored and used in such a way as to minimise the risks of contamination, or any alteration. During the establishment of the seed lot and cell bank, no other living or infectious material (e.g. virus or cell lines) should be handled simultaneously in the same area or by the same person.

iv) Establishment of the seed lot and cell bank should be performed in a suitable environment to protect the seed lot and the cell bank and, if applicable, the personnel handling it and the external environment. The master seed or the cell bank should consist of a single uniform batch or serial that has been mixed and filled into containers as one batch or serial.

v) Only authorised personnel should be allowed to handle the material and this handling should be done under the supervision of a competent person. Different seed lots or cell banks should be stored at the temperature that assures negligible degradation while taking care to avoid confusion or cross-contamination errors. It is desirable to split the seed lots and cell banks and to store the parts at different locations so as to minimise the risk of total loss. Storage equipment should be monitored for proper function and connected to an alarm system for immediate notification of malfunction.

1.6.1. Master seeds and working seeds

i) A master seed (reference culture, parental strain) should be established for each microorganism used in the production of a product to serve as the source of seed for inoculation of all production cultures. Records of the source of the master seed should be maintained. For each seed, the highest and lowest passage levels that may be used for production should be established and specified in the approved production documents for the relevant regulatory procedure.

ii) Working seeds and production seeds may be prepared from the master seed by subculturing. Using a master seed and limiting the number of passages of seed microorganism in this manner assists in maintaining uniformity and consistency in production.

iii) The origin, form and storage conditions of seed material should be described (frozen or desiccated and stored at low temperatures such as –40°C or –70°C, or under other conditions found to be optimal for maintaining viability). Storage containers should be

adequately sealed and clearly labelled. Storage conditions should be properly monitored. An inventory should be kept and each container accounted for. Tamper evident tape may be needed for boxes and containers.

iv) For genetically modified microorganisms, the source of the gene(s) for the immunogenic antigens and the vector microorganism should be identified. Furthermore, the gene sequences introduced into the seed microorganism genome during construction of the modified seed should be provided.

1.6.2. Master cell stocks

i) When cell cultures are used to prepare a product, a master cell stock (MCS) should be established for each type of cell to be used. Records of the source of the master cell stock should be maintained. For each product, the highest and lowest passage levels of cells that may be used for production should be established and specified in approved documents. Each MCS should be characterised to ensure its identity, and its genetic stability should be demonstrated when subcultured from the lowest to the highest passage used for production. The karyotype of the MCS should be shown to be stable with a low level of polyploidy. Freedom from oncogenicity or tumorogenicity should be demonstrated by *in-vivo* studies in appropriate species using the highest cell passage that may be used for production. Purity of MCSs should be established by testing to ensure freedom from extraneous bacteria, fungi, mycoplasma, and viruses.

1.6.3. Primary cells

i) Primary cells are defined as a pool of original cells derived from normal tissue up to and including the tenth subculture used in the production of biologicals.

ii) In the case of products for use in poultry, these cells are usually obtained from SPF embryonating chicken eggs that have originated in an unvaccinated flock subjected to intensive microbiological monitoring.

iii) Other primary cells are derived from normal tissue of healthy animals and are tested for contamination with a wide variety of microorganisms as appropriate, including bacteria, fungi, mycoplasmas, and cytopathic or haemadsorbing-inducing agents or other extraneous viruses. The use of primary cells has an inherently higher risk of introducing extraneous agents compared with the use of cell lines and should be avoided where alternative methods of producing effective vaccines exist. Indeed, some control authorities only allow the use of primary cells in exceptional cases.

1.6.4. Embryonated eggs

i) Embryonated eggs are also commonly used in the production of biologicals. They should be derived from SPF chicken flocks that have been intensively monitored for infectious agents and have not been vaccinated; or, where justified (e.g. for production of some inactivated vaccines) and in line with the marketing authorisation, from healthy chicken flocks. The route of inoculation of the egg and the choice of egg material to be harvested are dependent on the particular organism that is being propagated. Regulatory bodies may have requirements for sources of eggs, and for release testing of products grown on them.

1.7. Operating principles

i) The formation of droplets and the production of foam should be avoided or minimised during manufacturing processes. Centrifugation and blending procedures that can lead to droplet formation should be carried out in appropriate contained or clean or contained areas to prevent transfer of live organisms.

ii) Accidental spillages, especially of live organisms, must be dealt with quickly and safely. Validated decontamination procedures should be available for each organism. Where different strains of single bacterial species or very similar viruses are involved, the process needs to be validated against only one of them, unless there is reason to believe that they may vary significantly in their resistance to the agent(s) involved.

iii) Operations involving the transfer of materials such as sterile media, cultures or products, should be carried out in pre-sterilised closed systems wherever possible. Where this is not possible, transfer operations must be protected by laminar airflow work stations.

iv) Addition of media or cultures to biogenerators (fermenters) and other vessels should be carried out under carefully controlled conditions to ensure that contamination is not introduced. Care must be taken to ensure that vessels are correctly connected when addition of cultures takes place.

v) Where necessary, for instance when two or more fermenters are within a single area, sampling and addition ports, and connectors (after connection, before the flow of product, and again before disconnection) should be sterilised with steam.

vi) Documentation, equipment, glassware, the external surfaces of product containers and other such materials must be disinfected before transfer from a contained area using a validated method. Only the absolute minimum required to allow operations to GMP standards should enter and leave the area. If obviously contaminated, such as by spills or aerosols, or if the organism involved is an exotic, the paperwork must be adequately disinfected through an equipment pass, or the information transferred out by such means as photocopy or fax.

vii) Liquid or solid wastes such as the debris after harvesting eggs, disposable culture bottles, unwanted cultures or biological agents, are best sterilised or disinfected before transfer from a contained area. However, alternatives such as sealed containers or piping may be appropriate in some cases.

viii) Articles and materials, including documentation, entering a production room should be carefully controlled to ensure that only items concerned with production are introduced. There should be a system that ensures that articles and materials entering a room are reconciled with those leaving so that their accumulation within the room does not occur.

ix) Heat-stable articles and materials entering a clean or contained area should do so through a double-ended autoclave or oven. Heat-labile articles and materials should enter through an air-lock with interlocked doors where they are disinfected. Sterilisation of articles and materials elsewhere is acceptable provided that they are double wrapped and enter through an airlock with the appropriate precautions.

x) Precautions must be taken to avoid contamination or confusion during incubation. There should be a cleaning and disinfection procedure for incubators. Containers in incubators should be carefully and clearly labelled.

xi) With the exception of blending and subsequent filling operations (or when totally enclosed systems are used) only one live biological agent may be handled within a production room at any given time. Production rooms must be effectively disinfected between the handling of different live biological agents.

xii) Products should be inactivated by the addition of inactivant accompanied by sufficient agitation, with specified time and conditions. The mixture should then be transferred to a second sterile vessel, unless the container is of such a size and shape as to be easily inverted and shaken so as to wet all internal surfaces with the final culture or inactivant mixture.

xiii) Vessels containing inactivated products should not be opened or sampled in areas containing live biological agents. All subsequent processing of inactivated products should take place in clean areas (as defined in the paragraph related to aseptic preparation) or in enclosed equipment dedicated to inactivated products.

xiv) Methods for sterilisation, disinfection, virus removal and inactivation should be validated.

xv) Filling should be carried out as soon as possible following production. Containers of bulk product prior to filling should be sealed, appropriately labelled and stored under specified conditions of temperature.

xvi) There should be a system to assure the integrity and closure of containers after filling.

xvii) The capping of vials containing live biological agents must be performed in such a way that ensures that contamination of other products or escape of the live agents into other areas or the external environment does not occur.

xviii) There may be a delay between the filling of final containers and their labelling and packaging. Procedures should be specified for the storage of unlabelled containers in order to maintain process control and to ensure satisfactory storage conditions. Special attention should be paid to the storage of heat-labile or photosensitive products. Storage temperatures should be specified and monitored.

xix) For each stage of production, the yield of product should be reconciled with that expected from that process. Any unexpected discrepancies should be investigated.

2. Rules governing quality control

2.1. Principle

Quality control is concerned with sampling, specifications and testing as well as the organisation, documentation and release procedures that ensure that the necessary and relevant tests are carried out, and that materials are not released for use, nor products released for sale or supply, until their quality has been judged satisfactory.

Quality control is not confined to laboratory operations, but must be involved in all decisions that may concern the quality of the product. The independence of quality control from production is considered fundamental to the satisfactory operation of quality control.

2.2. General rules for veterinary medicinal products including vaccines

i) Each holder of a relevant regulatory approval should have a quality control department. This department should be independent from other departments, and under the authority of a person with appropriate qualifications, who has adequate laboratory support. Adequate resources must be available to ensure that all the quality control requirements are effectively and reliably carried out.

ii) The head of the quality control department generally has the following responsibilities:

   a) to approve or reject, as he/she sees fit, starting materials, packaging materials, and intermediate, bulk and finished products;

   b) to evaluate batch records;

   c) to ensure that all necessary testing is carried out;

   d) to approve specifications, sampling instructions, test methods and other quality control procedures;

   e) to approve and monitor any contract analysts;

   f) to check the maintenance of his/her department, premises and equipment;

   g) to ensure that the appropriate validations are done;

   h) to ensure that the required initial and continuing training of department personnel is carried out and adapted according to need.

iii) The quality control department may have other duties, such as to establish, validate and implement all quality control procedures, keep the reference samples of materials and products, provide training and SOPs or Directives to departments to ensure the correct labelling of containers of materials and products, ensure the monitoring of the stability of the products, and participate in the investigation of complaints related to the quality of the product. All these operations should be carried out in accordance with written procedures and recorded.

iv) Finished product assessment should include all relevant factors, including production conditions, results of in-process testing, a review of manufacturing (including packaging) documentation, compliance with finished product specifications and examination of the finished product.

v) In-process controls ensure the quality of product. Those controls should be performed at an appropriate stage of production.

vi) There may be a requirement for the continuous monitoring of data during a production process, for example monitoring of physical parameters during fermentation.

vii) Continuous culture of biological products is a common practice and special consideration needs to be given to the quality control requirements arising from this type of production method.

2.3. Good practice for quality control in laboratories

i) Control laboratory premises and equipment should meet the general and specific requirements for quality control areas given in this chapter.

ii) The personnel, premises, and equipment should be appropriate to the tasks imposed by the nature and the scale of the manufacturing operations. The use of outside laboratories, in conformity with the principles detailed in Chapter 2.3.3 *Minimum requirements for the organisation and management of a vaccine manufacturing facility,* Section 4. *Rules governing outsourced activities,* can be accepted for particular documented reasons.

2.3.1. Documentation

i) Laboratory documentation should follow the principles given in chapter 2.3.3, Section 3. *Rules governing documentation*. The following details should be available to the quality control department:

a) specifications;

b) sampling procedures;

c) testing procedures and records (including analytical worksheets or laboratory notebooks);

d) analytical reports or certificates;

e) data from environmental monitoring, where required;

f) validation records of test methods, where applicable;

g) procedures for and records of the calibration of instruments and maintenance of equipment.

ii) Any quality control documentation relating to a batch record should be retained for one year after the expiry date of the batch or at least 5 years after the certification. Records retention requirements may be specified by the relevant regulatory body or national laws.

iii) For some kinds of data (e.g. analytical tests results, yields, and environmental controls) it is recommended that records are kept in a manner permitting trend evaluation.

iv) In addition to the information that is part of the batch record, other original data such as laboratory notebooks or records should be retained and readily available

2.3.2. Sampling

i) Sampling should be done in accordance with approved written procedures that describe:

a) the method of sampling;

b) the equipment to be used;

c) the amount of the sample to be taken;

d) instructions for any required sub-division of the sample;

e) the type and condition of the sample container to be used;

f) the identification of containers sampled;

g) any special precautions to be observed, especially with regard to the sampling of sterile or noxious materials;

h) the storage conditions;

i) Instructions for the cleaning and storage of sampling equipment.

ii) Quality control personnel should have access to production areas for sampling and investigation.

iii) Samples are retained; firstly to provide a sample for analytical testing and secondly to provide a specimen of the fully finished product. Samples may therefore fall into two categories:

a) *Reference sample*: a sample of a batch of starting material, packaging material or finished product that is stored for the purpose of being analysed should the need arise during the shelf life of the batch concerned.

b) *Retention sample*: a sample of a fully packaged unit from a batch of finished product.

These are stored for identification and retest purposes during or beyond the shelf life of the product. The number of retention samples may be specified by the relevant regulatory authority, otherwise they should be stored at least in duplicate.

iv) Samples should be selected from each batch or serial of product. The selector should pick representative final containers from each batch or serial and store these samples at the storage temperature recommended on the label. The producer should keep these reserve samples at the recommended storage temperature for a minimum of 12 months after the expiry date shown on the label, so that they are available to assist in evaluating the cause of any field problems reported from the use of the vaccine. The samples should be stored in a secure storage area and be tamper-evident.

v) It may be necessary to retain samples of intermediate products in sufficient amount and under appropriate storage conditions to allow repetition or confirmation of a batch control.

vi) Samples should be representative of the batch of materials or products from which they are taken. Other samples may also be taken to monitor the most stressed part of a process (e.g. beginning or end of a process).

vii) Sample containers should bear a label indicating the contents, the batch number, the date of sampling and the containers from which samples have been drawn.

2.3.3. Testing

i) Analytical methods should be validated. All testing operations described in the relevant regulatory approval documents should be carried out according to the approved methods.

ii) The results obtained and associated calculations should be checked and recorded as satisfactory or not. If not, action should be taken according to the manufacturer's procedures.

iii) Records should include at least the following data:

a) name of the material or product and, where applicable, dosage form;

b) batch number and, where appropriate, the manufacturer or supplier;

c) references to the relevant specifications and testing procedures;

d) test results, including observations and calculations, and reference to any certificates of analysis;

e) dates of testing;

f) initials of the persons who performed the testing;

g) initials of the persons who verified the testing and the calculations, where appropriate;

h) a clear statement of release or rejection (or other status decision) and the dated signature of the designated responsible person.

iv) All the in-process controls and procedures should be performed according to methods approved by quality control and the results recorded.

2.4. Batch tests for immunological products

i) It may be necessary to retain samples of intermediate products in sufficient amount and under appropriate storage conditions to allow repetition or confirmation of a batch control.

ii) There may be a requirement for the continuous monitoring of data during a production process, for example monitoring of physical parameters during fermentation.

iii) Continuous culture of biological products is a common practice and special consideration needs to be given to the quality control requirements arising from this type of production method.

2.4.1. Batch or serial release for distribution

i) Prior to release, the manufacturer must test each batch or serial for purity, (safety if required), and potency, as well as perform any other tests described in the firm's Outline of Production or other documentation of the manufacturing process for that product. In countries that have national regulatory programs that include official control authority re-testing (check testing) of final products, samples of each batch or serial should also be submitted for testing in government laboratories by competent authorities. If unsatisfactory results are obtained for tests conducted either by the manufacturer or by competent authorities, the batch or serial should not be released. In such cases, subsequent batches or serials of the product should be given priority for check testing by competent authorities.

2.4.1.1. Batch or serial purity test

i) Purity is determined by testing for a variety of contaminants. Tests to detect contaminants are performed on: master seeds, primary cells, MCSs, ingredients of animal origin if not subjected to sterilisation (e.g. fetal bovine serum, bovine albumin, or trypsin), and each batch or serial of final product prior to release.

ii) Purity test procedures detailed in Chapter 1.1.9 *Tests for sterility and freedom from contamination of biological materials intended for veterinary use*.

iii) Procedures used to provide evidence that fetal or calf serum and other ingredients of bovine origin are free of pestiviruses are of great importance and should be well documented.

iv) Tests to be used to provide evidence of purity vary with the nature of the product, and should be prescribed in the Outline of Production or other documentation of the manufacturing process.

v) As tests for the detection of TSE agents in ingredients of animal origin have not been developed, vaccine manufacturers should document in their Outlines of Production or SOPs the measures they have implemented to minimise the risk of such contamination in ingredients of animal origin.

This relies on three principles:

a) first, verification that the animal source of all ingredients of animal origin in production facilities are from countries recognised as having the lowest possible risk of bovine spongiform encephalopathy;

b) second, that the tissues or other substances used are themselves recognised as being of low or nil risk of containing TSE agents;

c) third, where relevant, that the processes applied to the material have been validated for inactivation of TSE agents. Methods of production should also

document the measures taken to prevent cross contamination of low risk materials by higher risk materials during processing.

2.4.1.2. Batch or serial safety test

i) Safety tests are not required by many regulatory authorities for the release of each batch or serial where the seed-lot system is used. Other regulatory authorities may allow waiving of target animal batch safety tests in line with VICH GL50 and 55 and waiving of laboratory animal batch safety tests in line with VICH GL59 where alternative methods exist.

ii) Where required, standard procedures are used for safety tests in mice, guinea-pigs, cats, dogs, horses, pigs, and sheep and are generally conducted using fewer animals than are used in the safety tests required for licensing. Batches or serials are considered satisfactory if local and systemic reactions to vaccination with the batch or serial to be released are in line with those described in the relevant regulatory approval dossier and product literature.

2.4.1.3. Batch or serial potency test

i) Batch or serial potency tests, required for each batch or serial prior to release, are designed to correlate with the host animal vaccination–challenge efficacy studies.

ii) For inactivated viral or bacterial products, potency tests may be conducted in laboratory or host animals, or by means of quantitative *in-vitro* methods that have been validated reliably to correlate *in-vitro* quantification of important antigen(s) with *in-vivo* efficacy.

iii) The potency of live vaccines is generally measured by means of bacterial counts or virus titration.

iv) Recombinant DNA or biotechnology-based vaccines should also be tested. Live genetically modified organisms can be quantified like any other live vaccine by titration, and expressed products of recombinant technology are quantified by *in vitro* tests, which can be easier to perform compared with tests on naturally grown antigens because of the in-process purification of the desired product.

v) When testing a live bacterial vaccine for release for marketing, the bacterial count must be sufficiently greater than that shown to be protective in the master seed immunogenicity (efficacy) test to ensure that at any time prior to the expiry date, the count will be at least equal to that used in the immunogenicity test.

vi) When testing a live viral vaccine for release, the virus titre must, as a rule, be sufficiently greater than that shown to be protective in the master seed immunogenicity test in order to ensure that at any time prior to the expiry date, the titre will be at least equal to that used in the immunogenicity test.

vii) Some control authorities specify higher bacterial or viral content than these. It is evident that the appropriate release titre is primarily dependent on the required potency and secondarily dependent on the rate of decay of the bacteria or viruses in the vaccine, as indicated by the stability test.

viii) Standard requirements have been developed and published by competent authorities for potency testing several vaccines. These tests can be found in CFR Title 9 part 113, in the European Pharmacopoeia, and in this *Terrestrial Manual*.

2.4.2. Other tests

i) Depending on the form of vaccine being produced, certain tests may be indicated and should be provided as appropriate in the Outline of Production or other documentation of the manufacturing process.

These tests may concern:

a) The level of moisture contained in desiccated products,

b) The level of residual inactivant in killed products,

c) The complete inactivation of killed products, pH,

d) The level of preservatives and permitted antibiotics,

e) The physical stability of adjuvants,

f) The retention of vacuum in desiccated products,

g) A general physical examination of the final vaccine.

Tests for these purposes may also be found in this *Terrestrial Manual*.

ii) Samples taken for sterility testing should be representative of the whole of the batch, but should in particular include samples taken from parts of the batch considered to be most at risk of contamination, e.g. for products that have been filled aseptically, samples should include containers filled at the beginning and end of the batch and after any significant intervention,

iii) The sterility test applied to the finished product should only be regarded as the last in a series of control measures by which sterility is assured. The test should be validated for the product(s) concerned.

CHAPTER 2.3.5.

MINIMUM REQUIREMENTS FOR ASEPTIC PRODUCTION IN VACCINE MANUFACTURE

SUMMARY

This chapter provides requirements for aseptic production in the manufacture and quality control of veterinary vaccines in accordance with Chapter 1.1.8 Principles of veterinary vaccine production *and Chapter 2.3.4* Minimum requirements for the production and quality control of vaccines. *Manufacturers should use the recommendations as a basis for the elaboration of specific rules adapted to their individual needs.*

The manufacture of vaccines should be carried out in clean areas with controlled entry for personnel, equipment and materials. Clean areas should be maintained to an appropriate cleanliness standard and supplied with air that has passed through filters of an appropriate efficiency. Component preparation, product preparation and filling should be carried out in separate areas within the clean area. Manufacturing operations are conducted aseptically at some or all stages.

Clean areas for the manufacture of vaccines are classified into four grades according to the characteristics of the required environment. Each manufacturing operation requires an appropriate environmental cleanliness level in the operational state in order to minimise the risks of particulate or microbial contamination of the product or materials being handled. In order to meet operational conditions these areas should be designed to reach certain specified air-cleanliness levels in the resting state. The resting state is the condition where the installation is installed and operating, complete with production equipment but with no operating personnel present. The operational state is the condition where the installation is functioning in the defined operating mode with the specified number of personnel working. The operational and resting states should be defined for each clean room or suite of clean rooms.

The chapter sets out specific requirements for air quality, use of isolators, aseptic preparation, personnel, building design, equipment, sanitation, processing of materials, sterilisation and finishing of products.

SPECIFIC REQUIREMENTS FOR ASEPTIC PREPARATION

1. Principle

Most vaccines are injectable products, sterile or aseptically prepared. Their production should meet the following additional requirements for aseptic preparation.

Sole reliance for sterility or other quality aspects must not be placed on finished product test.

2. General

i) The manufacture of vaccines should be carried out in clean areas entry to which should be through airlocks for personnel or for equipment and materials. Clean areas should be maintained to an appropriate cleanliness standard and supplied with air that has passed through filters of an appropriate efficiency.

ii) The various operations of component preparation, product preparation and filling should be carried out in separate areas within the clean area. Manufacturing operations are conducted aseptically at some or all stages.

iii) Clean areas for the manufacture of vaccines are classified according to the required characteristics of the environment. Each manufacturing operation requires an appropriate environmental cleanliness level in the operational state in order to minimise the risks of particulate or microbial contamination of the product or materials being handled.

iv) In order to meet "in operation" conditions these areas should be designed to reach certain specified air-cleanliness levels in the "at rest" occupancy state. The "at-rest" state is the condition where the installation is installed and operating, complete with production equipment but with no operating personnel present. The "in operation" state is the condition where the installation is functioning in the defined operating mode with the specified number of personnel working.

v) The "in operation" and "at rest" states should be defined for each clean room or suite of clean rooms.

vi) For aseptic preparations four grades can be distinguished.

a) *Grade A:* The local zone for high risk operations, e.g. filling zone, stopper bowls, open ampoules and vials, making aseptic connections. Normally such conditions are provided by a laminar air flow work station. Laminar air flow systems should provide a homogeneous air speed in a range of 0.36 to 0.54 m/s (guidance value) at the working position in open clean room applications. The maintenance of laminarity should be demonstrated and validated.

A uni-directional air flow and lower velocities may be used in closed isolators and glove boxes.

b) *Grade B:* For aseptic preparation and filling, this is the background environment for the Grade A zone.

c) *Grade C and D:* Clean areas for carrying out less critical stages in the aseptic preparation.

3. Clean room and clean air device classification

i) Clean rooms and clean air devices should be classified in accordance with EN ISO 14644-1. Classification should be clearly differentiated from operational process environmental monitoring. The maximum permitted airborne particle concentration for each grade is given in the following table.

Maximum permitted number of particles per m^3 equal to or greater than the tabulated size				
	At rest		**In operation**	
Grade	**0.5 μm**	**5.0μm**	**0.5 μm**	**5.0μm**
A	3520	20	3520	20
B	3520	29	352,000	2900
C	352,000	2900	3,520,000	29,000
D	3,520,000	29,000	Not defined	Not defined

ii) For classification purposes in Grade A zones, a minimum sample volume of 1 m^3 should be taken per sample location. For Grade A the airborne particle classification is ISO 4.8 (as defined in ISO 14644-1) dictated by the limit for particles ≥5.0 μm. For Grade B (at rest) the airborne particle classification is ISO 5 for both considered particle sizes. For Grade C (at rest and in operation) the airborne particle classification is ISO 7 and ISO 8 respectively. For Grade D (at rest) the airborne particle classification is ISO 8. For classification purposes EN/ISO 14644-1 methodology defines both the minimum number of sample locations and the sample size based on the class limit of the largest considered particle size and the method of evaluation of the data collected.

iii) Portable particle counters with a short length of sample tubing should be used for classification purposes because of the relatively higher rate of precipitation of particles ≥5.0μm in remote sampling systems with long lengths of tubing. Isokinetic sample heads shall be used in unidirectional airflow systems.

iv) "In operation" classification may be demonstrated during normal operations, simulated operations or during media fills as worst-case simulation is required for this. EN ISO 14644-2 provides information on testing to demonstrate continued compliance with the assigned cleanliness classifications.

v) Clean rooms and clean air devices should be routinely monitored in operation, for the full duration of critical processing, except where justified by contaminants in the process that would damage the particle counter or present a hazard, e.g. live organisms. In such cases, monitoring during routine equipment set up operations should be undertaken prior to exposure to the risk. Monitoring during simulated operations should also be performed.

vi) Airborne particle monitoring systems may consist of independent particle counter; a network of sequentially accessed sampling points connected by manifold to a single particle counter; or a combination of the two.

vii) The sample sizes taken for monitoring purposes using automated systems will usually be a function of the sampling rate of the system used. It is not necessary for the sample volume to be the same as that used for formal classification of clean rooms and clean air devices.

viii) The particle limits given in the table for the "at rest" state should be achieved after a short "clean up" period of 15–20 minutes (guidance value) in an unmanned state after completion of operations.

ix) The monitoring of Grade C and D areas in operation should be performed in accordance with the principle of quality risk management. The requirements and alert or action limits will depend on the nature of the operations carried out, but the recommended "clean up period" should be attained.

x) Other characteristics such as temperature and relative humidity depend on the product and nature of the operations carried out. These parameters should not interfere with the defined cleanliness standard.

xi) Examples of operations to be carried out in the various grades include:

Grade	Examples of operations for aseptic preparations
A	Aseptic preparation and filling
C	Preparation of solutions to be filtered
D	Handling of components after washing

xii) Where aseptic operations are performed monitoring should be frequent using methods such as settle plates, volumetric air and surface sampling (e.g. swabs and contact plates). Sampling methods used in operation should not interfere with zone protection. Results from monitoring should be considered when reviewing batch documentation for finished product release. Surfaces and personnel should be monitored after critical operations. Additional microbiological monitoring is also required outside production operations, e.g. after validation of systems, cleaning and sanitisation.

Recommended limits for microbial monitoring of clean areas during operation:

Recommended limits for microbial contamination[(a)]				
Grade	**Air sample** CFU/m^3	**Settle plates** (diameter 90 mm) CFU/4 hours[(b)]	**Contact plates** (diameter 55 mm) CFU/plate	**Glove print** five fingers CFU/glove
A	< 1	< 1	< 1	< 1
B	10	5	5	5
C	100	50	25	–
D	200	100	50	–

[(a)]These are average values. [(b)]Individual settle plates may be exposed for less than 4 hours.
CFU= colony-forming unit

xiii) Appropriate alert and action limits should be set for the results of particulate and microbiological monitoring. If these limits are exceeded operating procedures should prescribe corrective action.

4. Isolator technology

i) The use of isolator technology to minimise human interventions in processing areas may result in a significant decrease in the risk of microbiological contamination of aseptically manufactured products from the environment. There are many possible designs of isolators and transfer devices. The isolator and the background environment should be designed so that the required air quality for the respective zones can be realised. Isolators are constructed of various materials more or less prone to puncture and leakage. Transfer devices may vary from a single door to double door designs to fully sealed systems incorporating sterilisation mechanisms.

ii) The transfer of materials into and out of the unit is one of the greatest potential sources of contamination. In general the area inside the isolator is the local zone for high risk manipulations, although it is recognised that laminar air flow may not exist in the working zone of all such devices.

iii) The air classification required for the background environment depends on the design of the isolator and its application. It should be controlled and for aseptic processing it should be at least Grade D.

iv) Isolators should be introduced only after appropriate validation. Validation should take into account all critical factors of isolator technology, for example the quality of the air inside and outside (background) the isolator, sanitisation of the isolator, the transfer process and isolator integrity.

v) Monitoring should be carried out routinely and should include frequent leak testing of the isolator and glove or sleeve system.

5. Aseptic preparation

i) Components after washing should be handled in at least a Grade D environment. Handling of sterile starting materials and components, unless subjected to sterilisation or filtration through a microorganism-retaining filter later in the process, should be done in a Grade A environment with Grade B background.

ii) Preparation of solutions that are to be sterile filtered during the process should be done in a Grade C environment; if not filtered, the preparation of materials and products should be done in a Grade A environment with a Grade B background.

iii) Handling and filling of aseptically prepared products should be done in a Grade A environment with a Grade B background.

iv) Prior to the completion of stoppering, transfer of partially closed containers as used in freeze drying should be done either in a Grade A environment with Grade B background or in sealed transfer trays in a Grade B environment.

6. Specific requirements for personnel working in clean areas

i) Only the minimum number of personnel required should be present in clean areas; this is particularly important during aseptic processing.

ii) All personnel (including those concerned with cleaning and maintenance) employed in such areas should receive regular training in disciplines relevant to the correct manufacture of vaccines. This training should include reference to hygiene and to the basic elements of microbiology. When outside staff who have not received such training (e.g. building or maintenance contractors) need to be brought in, particular care should be taken over their instruction and supervision.

iii) Staff who have been engaged in the processing of animal tissue materials or of cultures of micro-organisms other than those used in the current manufacturing process should not enter sterile-product areas unless rigorous and clearly defined entry procedures have been followed.

iv) High standards of personal hygiene and cleanliness are essential. Personnel involved in the manufacture of aseptic preparations should be instructed to report any condition that may cause the shedding of abnormal numbers or types of contaminants; periodic health checks for such conditions are desirable. Actions to be

taken about personnel who could be introducing undue microbiological hazard should be decided by a designated competent person.

v) Wristwatches, make-up and jewellery should not be worn in clean areas.

vi) Changing and washing should follow a written procedure designed to minimise contamination of clean area clothing or carry-through of contaminants to the clean areas.

vii) The clothing and its quality should be appropriate for the process and the grade of the working area. It should be worn in such a way as to protect the product from contamination.

viii) The description of clothing required for each grade is given below:

a) Grade D: Hair and, where relevant, beard should be covered. A general protective suit and appropriate shoes or overshoes should be worn. Appropriate measures should be taken to avoid any contamination coming from outside the clean area.

b) Grade C: Hair and where relevant beard and moustache should be covered. A single or two-piece trouser suit, gathered at the wrists and with high neck and appropriate shoes or overshoes should be worn. They should shed virtually no fibres or particulate matter.

c) Grade A/B: Headgear should totally enclose hair and, where relevant, beard and moustache; it should be tucked into the neck of the suit; a face mask should be worn to prevent the shedding of droplets. Appropriate sterilised, non-powdered rubber or plastic gloves and sterilised or disinfected footwear should be worn. Trouser-legs should be tucked inside the footwear and garment sleeves into the gloves. The protective clothing should shed virtually no fibres or particulate matter and retain particles shed by the body.

ix) Outdoor clothing should not be brought into changing rooms leading to Grade B and C rooms. For every worker in a Grade A/B area, clean sterile (sterilised or adequately sanitised) protective garments should be provided at each work session. Gloves should be regularly disinfected during operations. Masks and gloves should be changed at least for every working session.

x) Clean area clothing should be cleaned and handled in such a way that it does not gather additional contaminants that can later be shed. These operations should follow written procedures. Separate laundry facilities for such clothing are desirable. Inappropriate treatment of clothing will damage fibres and may increase the risk of shedding of particles.

7. Specific requirements for clean areas

i) In clean areas, all exposed surfaces should be smooth, impervious and unbroken in order to minimise the shedding or accumulation of particles or micro-organisms and to permit the repeated application of cleaning agents, and disinfectants where used.

ii) To reduce accumulation of dust and to facilitate cleaning there should be no uncleanable recesses and a minimum of projecting ledges, shelves, cupboards and equipment. Doors should be designed to avoid those uncleanable recesses; sliding doors may be undesirable for this reason.

iii) False ceilings should be sealed to prevent contamination from the space above them.

iv) Pipes and ducts and other utilities should be installed so that they do not create recesses, unsealed openings and surfaces that are difficult to clean.

v) Sinks and drains should be prohibited in Grade A/B areas used for aseptic manufacture. In other areas air breaks should be fitted between the machine or sink and the drains. Floor drains in lower grade clean rooms should be fitted with traps or water seals to prevent back-flow.

vi) Changing rooms should be designed as airlocks and used to provide physical separation of the different stages of changing and so minimise microbial and particulate contamination of protective clothing. They should be flushed effectively with filtered air. The final stage of the changing room should, in the at-rest state, be the same grade as the area into which it leads. The use of separate changing rooms for entering and

leaving clean areas is sometimes desirable. In general hand washing facilities should be provided only in the first stage of the changing rooms.

vii) Both airlock doors should not be opened simultaneously. An interlocking system or a visual or audible warning system should be operated to prevent the opening of more than one door at a time.

viii) A filtered air supply should maintain a positive pressure and an air flow relative to surrounding areas of a lower grade under all operational conditions and should flush the area effectively. Adjacent rooms of different grades should have a pressure differential of 10–15 Pascals (guidance values). Particular attention should be paid to the protection of the zone of greatest risk, that is, the immediate environment to which a product and cleaned components that contact the product are exposed. The various recommendations regarding air supplies and pressure differentials may need to be modified where it becomes necessary to contain some materials, e.g. live viruses or bacteria. Decontamination of facilities and treatment of air leaving a clean area may be necessary for some operations.

ix) It should be demonstrated that air-flow patterns do not present a contamination risk, e.g. care should be taken to ensure that air flows do not distribute particles from a particle-generating person, operation or machine to a zone of higher product risk.

x) A warning system should be provided to indicate failure in the air supply. Indicators of pressure differences should be fitted between areas where these differences are important. These pressure differences should be recorded regularly or otherwise documented.

8. Equipment

i) A conveyor belt should not pass through a partition between a Grade A or B area and a processing area of lower air cleanliness, unless the belt itself is continually sterilised (e.g. in a sterilising tunnel).

ii) As far as practicable equipment, fittings and services should be designed and installed so that operations, maintenance and repairs can be carried out outside the clean area. If sterilisation is required, it should be carried out, wherever possible, after complete reassembly.

iii) When equipment maintenance has been carried out within the clean area, the area should be cleaned, disinfected or sterilised where appropriate, before processing recommences if the required standards of cleanliness or asepsis have not been maintained during the work.

iv) Water treatment plants and distribution systems should be designed, constructed and maintained so as to ensure a reliable source of water of an appropriate quality. They should not be operated beyond their designed capacity.

v) All equipment such as sterilisers, air handling and filtration systems, air vent and gas filters, water treatment, generation, storage and distribution systems should be subject to validation and planned maintenance; their return to use should be approved.

9. Sanitation

i) The sanitation of clean areas is particularly important. They should be cleaned thoroughly in accordance with a written programme. Where disinfectants are used, more than one type should be employed. Monitoring should be undertaken regularly in order to detect the development of resistant strains.

ii) Disinfectants and detergents should be monitored for microbial contamination; dilutions should be kept in previously cleaned containers and should be stored and labelled according to specifications and expiry. Disinfectants and detergents used in Grades A and B areas should be sterile prior to use.

10. Processing

i) Preparations of microbiological origin should not be made or filled in areas used for the processing of other vaccines; however, vaccines of dead organisms or of bacterial extracts may be filled, after inactivation, in the same premises as other sterile medicinal products after appropriate cleaning.

ii) Validation of aseptic processing should include a process simulation test using a nutrient medium (media fill). Selection of the nutrient medium should be made based on dosage form of the product and selectivity, clarity, concentration and suitability for sterilisation of the nutrient medium.

iii) The process simulation test should imitate as closely as possible the routine aseptic manufacturing process and include all the critical subsequent manufacturing steps. It should also take into account various interventions known to occur during normal production as well as worst-case situations.

iv) Process simulation tests should be performed as initial validation with three consecutive satisfactory simulation tests per shift and repeated at defined intervals and after any significant modification to the HVAC-system, equipment, process and number of shifts. Normally process simulation tests should be repeated twice a year per shift and process.

v) The number of containers used for media fills should be sufficient to enable a valid evaluation. For small batches, the number of containers for media fills should at least equal the size of the product batch. The target should be zero growth[1]. For any run size, intermittent incidents of microbial contamination may be indicative of low-level contamination that should be investigated. Investigation of gross failures should include the potential impact on the sterility assurance of batches manufactured since the last successful media fill.

vi) Care should be taken that any validation does not compromise the processes.

vii) Water sources, water treatment equipment and treated water should be monitored regularly for chemical and biological contamination and, as appropriate, for endotoxins. Records should be maintained of the results of the monitoring and of any action taken.

viii) Activities in clean areas and especially when aseptic operations are in progress should be kept to a minimum and movement of personnel should be controlled and methodical, to avoid excessive shedding of particles and organisms due to over-vigorous activity. The ambient temperature and humidity should not be uncomfortably high because of the nature of the garments worn.

ix) Microbiological contamination of starting materials should be within a pre-specified range. Specifications should include requirements for microbiological quality when the need for this has been indicated by monitoring.

x) Containers and materials liable to generate fibres should be minimised in clean areas.

xi) Components, containers and equipment should be handled after the final cleaning process in such a way that they are not re-contaminated.

xii) The interval between the washing and drying and the sterilisation of components, containers and equipment as well as between their sterilisation and use should be minimised and subject to a time-limit appropriate to the storage conditions.

xiii) Components, containers, equipment and any other article required in a clean area where aseptic work takes place should be sterilised and passed into the area through double-ended sterilisers sealed into the wall, or by a procedure that achieves the same objective of not introducing contamination. Non-combustible gases should be passed through micro-organism retentive filters.

xiv) The efficacy of any new procedure should be validated, and the validation verified at scheduled intervals based on performance history or when any significant change is made in the process or equipment.

11. Sterilisation

i) All sterilisation processes should be validated. Particular attention should be given when the adopted sterilisation method is not described in the current editions of Pharmacopoeias, or when it is used for a product that is not a simple aqueous or oily solution. Where possible, heat sterilisation is the method of

1 A rationale to this topic can be found in the PIC/S guideline (PIC/S, 2014).

choice. In any case, the sterilisation process must be in accordance with the marketing and manufacturing authorisations.

ii) Before any sterilisation process is adopted its suitability for the product and its efficacy in achieving the desired sterilising conditions in all parts of each type of load to be processed should be demonstrated by physical measurements and by biological indicators where appropriate. The validity of the process should be verified at scheduled intervals, at least annually, and whenever significant modifications have been made to the equipment. Records should be kept of the results.

iii) For effective sterilisation the whole of the material must be subjected to the required treatment and the process should be designed to ensure that this is achieved.

iv) Validated loading patterns should be established for all sterilisation processes.

v) Biological indicators should be considered as an additional method for monitoring sterilisation. They should be stored and used according to the manufacturer's instructions, and their quality checked by positive controls. If biological indicators are used, strict precautions should be taken to avoid transferring microbial contamination from them.

vi) There should be a clear means of differentiating products that have not been sterilised from those that have. Each basket, tray or other carrier of products or components should be clearly labelled with the material name, its batch number and an indication of whether or not it has been sterilised. Indicators such as autoclave tape may be used, where appropriate, to indicate whether or not a batch (or sub-batch) has passed through a sterilisation process, but they do not give a reliable indication that the lot is, in fact, sterile.

vii) Sterilisation records should be available for each sterilisation run. They should be approved as part of the batch release procedure.

11.1. Sterilisation by heat

i) Each heat-sterilisation cycle should be recorded on a time/temperature chart with a sufficiently large scale or by other appropriate equipment with suitable accuracy and precision. The position of the temperature probes used for controlling or recording should have been determined during the validation, and where applicable also checked against a second independent temperature probe located at the same position.

ii) Chemical or biological indicators may also be used, but should not take the place of physical measurements.

iii) Sufficient time must be allowed for the whole of the load to reach the required temperature before measurement of the sterilising time-period is commenced. This time must be determined for each type of load to be processed.

iv) After the high temperature phase of a heat-sterilisation cycle, precautions should be taken against contamination of a sterilised load during cooling. Any cooling fluid or gas in contact with the product should be sterilised unless it can be shown that any leaking container would not be approved for use.

11.1.1. Moist heat

i) Both temperature and pressure should be used to monitor the process. Control instrumentation should normally be independent of monitoring instrumentation and recording charts. Where automated control and monitoring systems are used for these applications they should be validated to ensure that critical process requirements are met. System and cycle faults should be registered by the system and observed by the operator. The reading of the independent temperature indicator should be routinely checked against the chart recorder during the sterilisation period. For sterilisers fitted with a drain at the bottom of the chamber, it may also be necessary to record the temperature at this position, throughout the sterilisation period. There should be frequent leak tests on the chamber when a vacuum phase is part of the cycle.

ii) The items to be sterilised, other than products in sealed containers, should be wrapped in a material that allows removal of air and penetration of steam but that prevents recontamination after sterilisation. All parts of the load should be in contact with the sterilising agent at the required temperature for the required time.

iii) Care should be taken to ensure that steam used for sterilisation is of suitable quality and does not contain additives at a level that could cause contamination of product or equipment.

11.1.2. Dry heat

i) The process used should include air circulation within the chamber and the maintenance of a positive pressure to prevent the entry of non-sterile air. Any air admitted should be passed through a HEPA filter. Where this process is also intended to remove pyrogens, challenge tests using endotoxins could be used as part of the validation.

11.2. Sterilisation by radiation

i) Radiation sterilisation is used mainly for the sterilisation of heat-sensitive materials and products. Many medicinal products and some packaging materials are radiation-sensitive, so this method is permissible only when the absence of deleterious effects on the product has been confirmed experimentally. Ultraviolet irradiation is not normally an acceptable method of sterilisation.

ii) During the sterilisation procedure the radiation dose should be measured. For this purpose, dosimetry indicators that are independent of dose rate should be used, giving a quantitative measurement of the dose received by the product itself. Dosimeters should be inserted in the load in sufficient number and close enough together to ensure that there is always a dosimeter in the irradiator. Where plastic dosimeters are used they should be used within the time-limit of their calibration. Dosimeter absorbances should be read within a short period after exposure to radiation.

iii) Biological indicators may be used as an additional control

iv) Validation procedures should ensure that the effects of variations in density of the packages are considered.

v) Materials handling procedures should prevent mix-up between irradiated and non-irradiated materials. Radiation sensitive colour disks should also be used on each package to differentiate between packages that have been subjected to irradiation and those that have not.

vi) The total radiation dose should be administered within a predetermined time span.

12. Finishing

i) Partially stoppered freeze drying vials should be maintained under Grade A conditions at all times until the stopper is fully inserted.

ii) Containers should be closed by appropriately validated methods. Containers closed by fusion, e.g. glass or plastic ampoules should be subject to 100% integrity testing. Samples of other containers should be checked for integrity according to appropriate procedures.

iii) The container closure system for aseptically filled vials is not fully integral until the aluminium cap has been crimped into place on the stoppered vial. Crimping of the cap should therefore be performed as soon as possible after stopper insertion.

iv) As the equipment used to crimp vial caps can generate large quantities of non-viable particulates, the equipment should be located at a separate station equipped with adequate air extraction.

v) Vial capping can be undertaken as an aseptic process using sterilised caps or as a clean process outside the aseptic core. Where this latter approach is adopted, vials should be protected by Grade A conditions up to

the point of leaving the aseptic processing area, and thereafter stoppered vials should be protected with a Grade A air supply until the cap has been crimped.

vi) Vials with missing or displaced stoppers should be rejected prior to capping. Where human intervention is required at the capping station, appropriate technology should be used to prevent direct contact with the vials and to minimise microbial contamination.

vii) Restricted access barriers and isolators may be beneficial in assuring the required conditions and minimising direct human interventions into the capping operation.

viii) Containers sealed under vacuum should be tested for maintenance of that vacuum after an appropriate, pre-determined period.

ix) Filled containers of parenteral products should be inspected individually for extraneous contamination or other defects. When inspection is done visually, it should be done under suitable and controlled conditions of illumination and background. Operators doing the inspection should pass regular eye-sight checks, with spectacles if worn, and be allowed frequent breaks from inspection. Where other methods of inspection are used, the process should be validated and the performance of the equipment checked at intervals. Results should be recorded.

OIE LISTED DISEASES AND OTHER DISEASES OF IMPOTANCE MULTIPLE SPACIES

SECTION 3.1.

MULTIPLE SPECIES

CHAPTER 3.1.1.

ANTHRAX

SUMMARY

Description and importance of the disease: *Anthrax is primarily a disease of herbivorous animals, although all mammals, including humans, and some avian species can contract it. Mortality can be very high, especially in herbivores. The aetiological agent is the spore-forming, Gram-positive rod-shaped bacterium,* Bacillus anthracis*. The disease has world-wide distribution and is a zoonosis.*

The disease is mediated mainly by exotoxins. Peracute, acute, subacute and, rarely, chronic forms of the disease are reported. Ante-mortem clinical signs may be virtually absent in peracute and acute forms of the disease. Subacute disease may be accompanied by progressive fever, depression, inappetence, weakness, prostration and death. Acute, subacute, and chronic disease may show localised swelling and fever. In chronic disease, the only sign may be enlarged lymph glands.

Detection and identification of the agent: Bacillus anthracis *is readily isolated in relatively high numbers from blood or tissues of a recently dead animal that died of anthrax, and colony morphology of* B. anthracis *is quite characteristic after overnight incubation on blood agar. The colony is relatively large, measuring approximately 0.3–0.5 cm in diameter. It is grey-white to white, non-haemolytic with a rough, ground-glass appearance and has a very tacky, butyrous consistency. The vegetative cells of* B. anthracis *are large, measuring 3–5 μm in length and approximately 1 μm in width. Ellipsoidal central spores, which do not swell the sporangium, are formed at the end of the exponential cell growth phase. The cells stain strongly Gram positive, and long chains are often seen* in vitro*, while paired or short chains are seen* in vivo*. Visualisation of the encapsulated bacilli, usually in large numbers, in a blood smear stained with azure B or polychrome methylene blue* (*M'Fadyean's reaction*) *is fully diagnostic.*

Serological tests: *Antibody detection in serum from infected animals is rarely used for diagnostic purposes and is essentially a research tool. The predominant procedure used is the enzyme-linked immunosorbent assay.*

Requirements for vaccines: *The most widely used livestock anthrax vaccine developed by Max Sterne in 1937 is a live, non-encapsulated, spore former held in suspension. In Russia and Eastern Europe, an equivalent type of vaccine is used* (*strain 55*)*. A list of producers is given in the World Health Organization anthrax guidelines.*

A. INTRODUCTION

Anthrax, an acute bacterial disease primarily of herbivores, is transmissible to humans. The aetiological agent, *Bacillus anthracis*, is a Gram-positive spore-forming rod-shaped bacterium. Anthrax is known by many names around the world including charbon, woolsorters' disease, ragpickers' disease, malignant carbuncle, malignant pustule and Siberian ulcer.

Animals become infected by ingesting spores, or possibly by being bitten by blood feeding insects such as stable flies (*Stomoxys calcitrans*) and mosquitoes (*Aedes aegypti* and *Aedes taeniorhynchus*) that have fed on an infected

animal or carcass. Infected animals are usually found dead as death can occur within 24 hours. To avoid environmental contamination with spores, post-mortem examinations of carcasses of animals suspected to have died of anthrax are discouraged and natural orifices such as mouth, nostril and anus should be closed (for example plugged with cotton wool or other suitable material soaked in an approved disinfectant) to prevent the formation of spores. There are regulations in most countries that prohibit post-mortem examination when anthrax is suspected. Recently dead animals may show any number of lesions, none of which is pathognomonic or entirely consistent.

Lesions most commonly seen are those of a generalised septicaemia often accompanied by an enlarged spleen with a dark semi-fluid pulp ('blackberry jam' consistency) and poorly clotted blood. Haemorrhage from the nose, mouth, vagina and/or anus at death may be found.

Gram-positive rod-shaped *B. anthracis* is an obligate pathogen. Most of the other species of *Bacillus* are common ubiquitous environmental saprophytes, although a number, notably *B. cereus, B. licheniformis* and *B. subtilis*, are occasionally associated with food poisoning in humans and with other clinical manifestations in both humans and animals.

1. Zoonotic risk and biosafety requirements

More than 95% of human anthrax cases take the cutaneous form and result from handling infected carcasses or hides, hair, meat or bones from such carcasses. *Bacillus anthracis* is not invasive and requires a lesion to infect. Protection for veterinarians and other animal handlers involves wearing gloves and other protective clothing (including full personal protective equipment [PPE] depending on the situation) when handling specimens from suspected anthrax carcasses and never rubbing the face or eyes. The risk of gastrointestinal anthrax may arise if individuals eat meat from animals infected with anthrax.

The risk of inhaling infectious doses becomes significant in occupations involving the processing of animal by-products for manufacturing goods (industrial anthrax). These include the tanning, woollen, animal hair, carpet, bone processing, and other such industries, where the potential for aerosolisation of substantial numbers of spores increases the risk of exposure to infectious doses. It is important that industrial workers use appropriate personal protective clothing and equipment and follow standard operating procedures that minimise the risk of transmission. Efficient air extraction equipment should be positioned over picking, combing, carding and spinning machines. Air blowing machinery should never be used for cleaning equipment due to the risk of spore dispersal.

Clinical specimens and cultures of *B. anthracis* should be handled with appropriate biosafety and containment procedures as determined by biorisk analysis (see Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*). Vaccination of laboratory personnel is recommended.

B. DIAGNOSTIC TECHNIQUES

Table 1. Test methods available for the diagnosis of anthrax and their purpose

Method	Purpose					
	Population freedom from infection	Individual animal freedom from infection prior to movement	Contribute to eradication policies	Confirmation of clinical cases	Prevalence of infection – surveillance	Immune status in individual animals or populations post-vaccination
Identification of the agent[(a)]						
Demonstration of capsule	–	–	–	++	–	–
Demonstration of lack of motility	–	–	–	++	–	–
Gamma phage lysis	–	–	–	++	–	–

Method	Purpose					
	Population freedom from infection	Individual animal freedom from infection prior to movement	Contribute to eradication policies	Confirmation of clinical cases	Prevalence of infection – surveillance	Immune status in individual animals or populations post-vaccination
Penicillin susceptibility	–	–	–	++	–	–
PCR	–	–	–	++	+++/++	–

Key: +++ = recommended for this purpose; ++ recommended but has limitations;
+ = suitable in very limited circumstances; – = not appropriate for this purpose.
PCR = polymerase chain reaction.
[(a)]A combination of agent identification methods applied on the same clinical sample is recommended.

1. Identification of the agent

Demonstration of encapsulated *B. anthracis* in smears of blood or tissues from fresh anthrax-infected carcasses and growth of the organism on blood agar plates is relatively uncomplicated and within the capability of most bacteriology laboratories. Difficulty may be encountered in the case of pigs and carnivores in which the terminal bacteraemia is frequently not marked, or in animals that received antibiotics before death.

Recovery of *B. anthracis* from old decomposed carcasses, processed specimens (bone meal, hides), or environmental samples (contaminated soil) is often difficult, requiring demanding and labour-intensive procedures. However live spores may be recovered from the turbinate bones of dead livestock and wildlife for an extended period after death (M. Hugh-Jones, personal communication).

1.1. Culture and identification of *Bacillus anthracis*

1.1.1. Fresh specimens

Bacillus anthracis grows readily on most types of nutrient agar, however, 5–7% horse or sheep blood agar is the diagnostic medium of choice. Blood is the primary clinical material to examine. Swabs of blood, other body fluids or swabs taken from incisions in tissues or organs can be spread over blood agar plates. After overnight incubation at 37°C, *B. anthracis* colonies are grey-white to white, 0.3–0.5 cm in diameter, non-haemolytic, with a ground-glass surface, and very tacky when teased with an inoculating loop. Tailing and prominent wisps of growth trailing back toward the parent colony, all in the same direction, are sometimes seen. This characteristic has been described as a 'medusa head' or 'curled hair' appearance. Confirmation of *B. anthracis* should be accomplished by the demonstration of a capsulated, spore-forming, Gram-positive rod in blood culture. Absence of motility is an additional test that can be done.

Anthrax-specific phages were first isolated in the 1950s, and the specifically named gamma phage was first reported in 1955 (Brown & Cherry, 1955) and quickly became the standard diagnostic phage for anthrax. Gamma phage belongs to a family of closely related anthrax phages (World Health Organization [WHO], 2008).

Two tests for confirming the identity of *B. anthracis* are gamma phage lysis and penicillin susceptibility. The typical procedure for these tests is to plate a lawn of suspect *B. anthracis* on a blood or nutrient agar plate and place a 10–15 µl drop of the phage suspension on one side of the lawn and a 10-unit penicillin disk to the other side. Allow the drop of phage suspension to soak into the agar before incubating the plate at 37°C. A control culture, e.g. the Sterne vaccine or the NCTC strain 10340, should be tested at the same time as the suspect culture to demonstrate the expected reaction for gamma phage lysis and penicillin susceptibility. If the suspect culture is *B. anthracis*, the area under the phage will be devoid of bacterial growth, because of lysis, and a clear zone will be seen around the penicillin disk indicating antibiotic susceptibility. Note that some field isolates of *B. anthracis* may be phage resistant or penicillin resistant. As the performance of the gamma phage lysis assay may be affected by the density of bacterial inoculum, Abshire *et al.* (2005) recommend streaking the suspect culture on the agar plate over several quadrants instead of using a lawn format and inoculating a drop of gamma phage on the

first and second quadrants on the plate. If antibiotic or phage resistant *B. anthracis* is suspected then polymerase chain reaction (PCR) diagnostic methods may be applied.

Phage suspensions may be obtained from central veterinary laboratories or central public health laboratories.

The phage can be propagated and concentrated by the following protocol. Store phage at 2–4°C and do not freeze phage as it will quickly become non-viable.

1.1.1.1. Stage one

i) Spread a blood agar (BA) plate of the Sterne vaccine strain of *B. anthracis*. Incubate overnight at 37°C.

ii) Inoculate approximately 10 ml of nutrient broth (NB) with growth from the BA plate and incubate at 37°C for approximately 4 hours or until just cloudy, then refrigerate.

iii) Spread 100 µl of the culture from step ii on three pre-dried BA plates and incubate at 37°C for 30–60 minutes.

iv) Spread 100 µl of the phage suspension to be amplified over the same plates. Incubate at 37°C overnight.

v) Harvest the phage-lysed growth on the BA plate in 5 ml of NB followed by a second 'wash' of 5 ml NB. Incubate at 37°C overnight.

vi) Filter (0.45 µm) and count by dropping 20 µl drops (three drops per dilution) of tenfold dilutions of the filtrate in saline onto lawns of the *B. anthracis* culture prepared as in step iii.

1.1.1.2. Stage two

This is essentially the same procedure as Stage one, only uses the filtrate from step vi to harvest the phage from the plates.

vii) Prepare three Sterne strain lawns on BA, as in step iii. Incubate at 37°C for 30–60 minutes.

viii) Spread 100 µl phage from step vi. Incubate at 37°C overnight.

ix) To 9 ml of filtrate from step vi, add 1 ml of 10× concentrated NB.

x) Harvest the phage from step viii with 5 ml of the solution from step ix, followed by a second 5 ml wash with the rest of the solution from step vi.

xi) Add 10 ml of 1× NB.

xii) Incubate at 37°C overnight, filter and count.

1.1.1.3. Stage three

xiii) Inoculate 100 ml of brain–heart infusion broth with approximately 2.5 ml of the culture from step ii. Incubate on a rotary shaker at 37°C until just turbid.

xiv) Add the 20 ml of filtrate from step xii and continue incubation overnight.

xv) The resultant filtrate is checked for sterility and titrated in tenfold dilutions on lawns of the vaccine strain as in step vi to determine the concentration of the phage. This should be of the order of 10^8–10^9 plaque forming units per ml.

1.1.2. Capsule visualisation

Virulent encapsulated *B. anthracis* is present in tissues and blood and other body fluids from animals that have died from anthrax. Thin smears may be prepared from blood from ear veins or other peripheral veins, exudate from orifices and, for horses and pigs, from oedematous fluid or superficial lymph nodes in the neck region. However if the animal has been dead more than 24 hours, the capsule may be difficult to detect. The bacteria should be looked for in smears of these specimens that have been dried, fixed and then stained with azure B (M'Fadyean's reaction). The capsule stains pink, whereas the bacillus cells stain dark blue. The cells are found in pairs or short chains and are often square-ended (the chains are sometimes likened to a set of railway

carriages – so-called 'box-car' or 'jointed bamboo-rod' appearance). Gram stain does not reveal the capsule. The capsule is not present on *B. anthracis* grown aerobically on nutrient agar or in nutrient broths but can be seen when the virulent bacterium is cultured for a few hours in a few millilitres of blood (defibrinated horse or sheep blood seems to work best). Alternatively, the capsule is produced when the virulent *B. anthracis* is cultured on nutrient agar containing 0.7% sodium bicarbonate and incubated in the presence of CO_2 (20% is optimal, but a candle jar works well). The agar is prepared by weighing nutrient agar base powder required for a final volume of 100 ml but reconstituting the measured agar in only 90 ml of water. Autoclave and cool to 50°C in a water bath. Add 10 ml of a filter-sterilised (0.22–0.45 µm filter) 7% solution of sodium bicarbonate. Mix and pour into Petri dishes. The encapsulated *B. anthracis* will form mucoid colonies and the capsule can be visualised by making thin smears on microscope slides, fixing, and staining with azure B or polychrome methylene blue (M'Fadyean's stain).

Polychrome methylene blue can be prepared as follows: 0.3 g of methylene blue is dissolved in 30 ml of 95% ethanol; 100 ml of 0.01% potassium hydroxide (KOH) is mixed with the methylene blue solution. Ideally, this should be allowed to stand exposed to the air, with occasional shaking, for at least 1 year to oxidise and mature. Addition of K_2CO_3 (to a final concentration of 1%) hastens the 'ripening' of the stain, but before it is regarded as diagnostically reliable, its efficacy should be established by testing it in parallel with an earlier, functional batch of stain on *bona fide* samples. It has been found that stains that give positive reactions with cultures of *B. anthracis* cultured artificially in horse blood sometimes do not give positive results in the field.

The method for capsule visualisation has been revised according to the description by Owen *et al.* (2013). The established simple polychrome methylene blue (PMB) staining method for blood or tissue smears from dead animals (M'Fadyean's reaction) is therefore replaced by azure B staining. It must be noted that the rarity of anthrax disease worldwide due to improvements in the control of the disease has led to quality controlled commercially produced PMB being difficult to obtain. In addition, reports of inaccurate results using alternative methylene blue-based stains has also become a concern. Hence, for laboratories requiring a reliable M'Fadyean stain for rapid detection, the recommended approach is to use commercially pure azure B (Owen *et al.,* 2013).

This microscopy method was validated by Aminu *et al.* (2020), for the detection of *B. anthracis* in field-collected blood smears. Four capsule-staining techniques were evaluated in an investigation of livestock mortalities suspected to be caused by anthrax. Field-prepared blood samples were tested by microscopy and the results indicated that the median sensitivity and specificity of microscopy using azure B were found to be comparable with those of the recommended standard, polychrome methylene blue (Aminu *et al.* 2020).

Azure B stain is prepared by constituting into a solution of 0.03 g azure B in 3 ml of 95% ethanol or methanol to which is then added 10 ml of 0.01% KOH (0.23% final azure B concentration). This can then be used immediately and throughout the tests. If stored in the dark at room temperature, the shelf life is at least 12 months. Smears to be stained should be fixed with ethanol or methanol (95–100%), not by heat, and the stain left for 5 minutes before washing off for optimum effect (Owen *et al.,* 2013).

In making smears for staining, only small drops of blood or tissue fluid are needed, and a thin, small smear is best. After fixing by dipping the smear in 95–100% alcohol for about 5 minutes and drying, a small (approximately 20 µl) drop of stain is placed on the smear and spread over it with an inoculating loop. After 5 minutes, the stain is washed with water, blotted, air-dried, and observed initially using the ×10 objective lens under which the short chains appear like short hairs; once found, these can be observed under oil immersion (×1000) for the presence of the pink capsule surrounding the blue/black-staining bacilli. To avoid laboratory contamination, the slide and blotting paper should be autoclaved or left for some hours in a 10% sodium hypochlorite solution.

1.1.3. Other specimens

Identification of *B. anthracis* from old, decomposed specimens, processed materials, and environmental samples, including soil, is possible but these samples often have saprophytic contaminants that outgrow and obscure *B. anthracis* on non-selective agars. The following procedure is suggested:

i) The sample is blended in two volumes of sterile distilled or deionised water and placed in a water bath at 62.5 ± 0.5°C for 15–30 minutes. Turnbull *et al.* (2007) have demonstrated that heat activation of spores can be conducted at a temperature range of 60–70°C with holding times not exceeding 15–30 minutes for best recovery.

ii) Tenfold dilutions to 10^{-2} or 10^{-3} are then prepared. From each dilution, 10–100 µl are plated on to blood agar and optionally 250–300 µl on to PLET agar (polymyxin, lysozyme, EDTA [ethylene diamine tetra-acetic acid], thallous acetate) (Knisely, 1966; WHO, 2008). All plates are incubated at 37°C. For combined selection and differentiation, blood agar-based media can provide advantages. In addition, PLET agar contains the toxic thallium acetate. An alternative for this is the so-called TSPB agar, a blood agar that has high selectivity against Gram-negative bacteria due to the addition of trimethoprim, sulfamethoxazole and polymyxin B (Hudson *et al.,* 2007; Rosenblatt & Stewart, 1974). TSPB agar is prepared by dissolving 40 g/litre nutrient agar base (e.g. SIFIN). The mixture is autoclaved and uniformly cooled to 45°C before adding 50 ml/litre sterile sheep blood (5%), trimethoprim (13.1 mg/litre), sulfamethoxazole (20 mg/litre) and polymyxin B (30,000 IU/litre). After mixing thoroughly, the agar is dispensed into Petri dishes.

iii) Blood agar plates are examined for typical colonies as previously described after overnight incubation, and the PLET plates are examined after 40–48 hours. Confirmation of the identity of suspect colonies as *B. anthracis* is done as described above.

PLET medium (Knisely, 1966; WHO, 2008) is prepared by using heart-infusion agar base (DIFCO) made up to the manufacturer's instructions with the addition of 0.25–0.3 g/litre EDTA and 0.04 g/litre thallous acetate. The mixture is autoclaved and uniformly cooled to 50°C before adding the polymyxin at o30,000 units/litre and lysozyme at 300,000 units/litre. After mixing thoroughly, the agar is dispensed into Petri dishes.

Reports of procedures for direct detection of *B. anthracis* in soils and other environmental specimens using the PCR are emerging. None of these has become routinely applicable at the present time.

Animal inoculation may be considered for recovery of *B. anthracis* if all other methods fail. Examples of when this might occur are specimens from animals that received antibiotic therapy before death or environmental samples containing sporostatic chemicals. Due to the increasing concern to eliminate the use of animals for biological testing, this approach should be used as a last resort and only if justified. Adult mice or guinea-pigs are the animals of choice. If the samples involved are soils, the animals should be pretreated, the day before testing, with both tetanus and gas gangrene antiserum. The samples are prepared as described for culturing, including heat-shocking at 62.5°C for 15 minutes. Mice are injected subcutaneously with 0.05–0.1 ml; guinea-pigs are inoculated intramuscularly with up to 0.4 ml (0.2 ml in each thigh muscle). Any *B. anthracis* present will result in death in 48–72 hours and the organism can be cultured from the blood as described above.

1.2. Immunological detection and diagnosis

It needs to be borne in mind that *B. anthracis* is antigenically very closely related to *B. cereus,* which is considered a ubiquitous component of the environmental microflora. The only unshared antigens that lend themselves to differentiating these two species by immunological approaches are the anthrax toxin antigens, produced during the exponential phase of growth, and the capsule of *B. anthracis*. This places considerable constraints on the extent to which immunological methods can be used in routine detection methodology.

1.2.1. Ascoli test

Ascoli (1911) published a procedure for the detection of thermostable anthrax antigen in animal tissue being used for by-products. This uses antiserum raised in rabbits to produce a precipitin reaction. The test lacks high specificity, in that the thermostable antigens of *B. anthracis* are shared by other *Bacillus* spp., and is dependent on the probability that only *B. anthracis* would proliferate throughout the animal and deposit sufficient antigen to give a positive reaction. This test appears to be used only in Eastern Europe.

To perform the Ascoli test, put approximately 2 g of sample in 5 ml of saline containing 1/100 final concentration of acetic acid and boil for 5 minutes. The resultant solution is cooled and filtered through filter paper. A few drops of rabbit antiserum (see preparation below) are placed in a small test tube. The filtrate from the previous step is gently layered over the top of the antiserum. A positive test is the formation of a visible precipitin band in under 15 minutes. Positive and negative control specimen suspensions should be included.

Antiserum is prepared in rabbits by the subcutaneous inoculation of Sterne anthrax vaccine on days 1 and 14. On days 28 and 35, the rabbits receive 0.5 ml of a mixture of several strains of virulent *B. anthracis* not exceeding 10^5 colony-forming units (CFU)/ml suspended in saline. Alternatively, the live virulent bacteria can be inactivated by prolonged suspension in 0.2% formalised saline, but the antigen mass needs to be increased to 10^8–10^9 CFU/ml. The suspension should be checked for inactivation of the *B. anthracis* before animal inoculation by culture of 0.1 ml into 100 ml of nutrient broth containing 0.1% histidine and, after incubation at 37°C for 7 days, subculture on to blood or nutrient agar. The dose regimen for the formalised suspension after initial vaccination on days 1 and 14 is increasing doses of 0.1, 0.5, 1, and 2 ml given intravenously at intervals of 4–5 days. Following either procedure, a test bleed at 10 days after the last injection should determine whether additional 2 ml doses should be administered to boost the precipitin titre.

1.2.2. Immunofluorescence

While some success has been achieved with immunofluorescence for capsule observation in the research situation (Ezzell & Abshire, 1996), it does not lend itself to routine diagnosis.

1.3. Confirmation of virulence with the polymerase chain reaction

Confirmation of virulence can be carried out using the PCR. The following instructions are taken from the WHO (2008). Template DNA for PCR can be prepared from a fresh colony of *B. anthracis* on nutrient agar by suspension of a loop of growth in 25 µl sterile deionised (or distilled) water and heating to 95°C for 20 minutes. Following cooling to approximately 4°C, and brief centrifugation, the supernatant can be used for the PCR reaction.

Examples of suitable primers (Beyer *et al.,* 1996; Hutson *et al.,* 1993) for confirming the presence of the pXO1 and pXO2 plasmids are given in the table below.

Target	Primer ID	Sequence (5' → 3')	Product size	Concentration
Protective antigen (PA)	PA 5 3048–3029	TCC-TAA-CAC-TAA-CGA-AGT-CG	596 bp	1 mM
	PA 8 2452–2471	GAG-GTA-GAA-GGA-TAT-ACG-GT		
Capsule	1234 1411–1430	CTG-AGC-CAT-TAA-TCG-ATA-TG	846 bp	0.2 mM
	1301 2257–2238	TCC-CAC-TTA-CGT-AAT-CTG-AG		

PCR can be carried out in 50 µl volumes using the above primers, 200 µM each of dATP, dCTP, dTTP and dGTP, 1.5 mM $MgCl_2$ and 2.5 units of DNA polymerase, all in NH_4 buffer, followed by the addition of 5 µl of template DNA. A 2% agarose gel has been found to work best with these small fragments.

Alternatively, premixed, predispensed, dried beads available commercially can be used. These are stable at room temperature, containing all the necessary reagents, except primer and template, for performing 25 µl PCR reactions. The template can be added in a 2.5 µl volume.

The following PCR cycle can be used: 1 × 95°C for 5 minutes; 30 × 95°C for 0.5 minute followed by 55°C for 0.5 minute followed by 72°C for 0.5 minute; 1 × 72°C for 5 minutes; cool to 4°C.

It should be noted that the primers given in the table above have proved successful for confirming the presence or absence of pXO1 and/or pXO2 in pure cultures of isolates from animal (including human) specimens or environmental samples. They may be unsuitable, however, for direct detection of *B. anthracis* in such specimens or samples. A choice of alternatives can be found in Jackson *et al.* (1998) and Ramisse *et al.* (1996). For the rare possibility that an isolate may lack both pXO1 and pXO2, a chromosomal marker should also be run; primers for these are also described in Jackson *et al.* (1998) and Ramisse *et al.* (1996). Ågren *et al*. (2013) published a very comprehensive study on the *in-silico* and *in-vitro* evaluation of 35 PCR-based methods for 20 chromosomal markers of *B. anthracis*. The PL3 (target: part of pro-phage type 3) assay (Wielinga *et al*., 2011) was identified as one of the best performing assays in this study and could be used for routine diagnostics.

Real-time PCR assays have been developed for enhanced speed, sensitivity and specificity of detection of pXO1, pXO2 and chromosomal genes of *Bacillus anthracis* and other closely related *Bacillus* spp. (e.g. Hadjinicolaou *et al*., 2009; Hoffmaster *et al*., 2002; Irenge *et al*., 2010; Qi *et al*., 2001; Rao *et al*., 2010). Selection of a particular assay will be dependent on the fitness for purpose and source of starting material (e.g. isolates, clinical specimen, environmental sample), requirement to differentiate from other *Bacillus* spp. or vaccine strains, demonstration of genetic diversity or confirmation of isolate identity. It is important that the laboratory conducting real-time PCR evaluate the performance of the test for their purpose and complete a validation analysis to ensure that it has been optimised and standardised for its intended use (see Chapter 1.1.6 *Validation of diagnostic assays for infectious diseases of terrestrial animals*).

Molecular typing techniques for *B. anthracis* like canonical single-nucleotide polymorphisms typing (e.g. Van Ert *et al*., 2007) and variable number tandem repeat analysis (e.g. Keim *et al*., 2000) are appropriate for use in specialised laboratories. Molecular typing based on whole genome sequencing e.g. core genome multilocus sequence typing may be useful to elucidate the diversity of *B. anthracis* genotypes circulating, to determine connections between outbreak events and supports infection chain tracing (Abdel-Glil *et al*., 2021).

C. REQUIREMENTS FOR VACCINES

1. Background

1.1. Rationale and intended use of the product

The most widely used vaccine for prevention of anthrax in animals was developed by Sterne (1937). He derived a rough variant of virulent *B. anthracis* from culture on serum agar in an elevated CO_2 atmosphere. This variant, named 34F2, was incapable of forming a capsule and was subsequently found to have lost the pXO2 plasmid, which codes for capsule formation. It has become the most widely used strain world-wide for animal anthrax vaccine production. In Central and Eastern Europe, an equivalent $pXO2^-$ derivative, Strain 55, is the active ingredient of the current livestock vaccine. A list of manufacturers of anthrax vaccine for use in animals is given in Annex 5 of WHO (2008).

The following information concerning preparation of the anthrax vaccine for use in animals is based on Misra (1991) and the WHO (1967). Generalised procedures are given; national regulatory authorities should be consulted in relation to Standard Operating Procedures that may pertain locally.

2. Outline of production and minimum requirements for conventional vaccines

2.1. Characteristics of the seed

2.1.1. Biological characteristics

Anthrax vaccine production is based on the seed-lot system. A seed lot is a quantity of spores of uniform composition processed at one time and maintained for the purpose of vaccine preparation. Each seed lot is no more than three passages from the parent culture and must produce a vaccine that is efficacious and safe for use in animals. It is recommended that a large

seed lot be prepared from the parent strain and preserved by lyophilisation for future production lots. The parent culture can be purchased[1].

2.1.2. Quality criteria

The seed lot is acceptable for anthrax vaccine if a vaccine prepared from the seed lot or a suspension harvested from a culture derived from a seed lot meets the requirements for control of final bulk with respect to freedom from bacterial contamination, safety and efficacy (immunogenicity).

2.2. Method of manufacture

2.2.1. Procedure

i) Preparation of the master seed

Seed lots are cultured on solid media formulated to promote sporulation of the organism. The solid medium formula for casein digest agar (sporulation agar) given in Misra (1991) is: 50 g tryptic digest of casein; 10 g yeast extract; 0.1 g $CaCl_2.6H_2O$; 0.01 g $FeSO_4.7H_2O$; 0.05 g $MgSO_4.7H_2O$; 0.03 g $MnSO_4.4H_2O$; 5.0 g K_2HPO_4; 1.0 g KH_2PO_4; 22 g agar; 1000 ml deionised or distilled water. The ingredients are dissolved in the water with the appropriate amount of heating; the solution is adjusted to pH 7.4, distributed into Roux bottles (120 ml per bottle) or other appropriate container, sterilised by autoclaving and cooled in the horizontal position. After the agar has solidified, excess liquid should be removed aseptically and the bottles left in an incubator (37°C) for at least 2 days to dry and to check the sterility.

Volumes of 2 ml of vaccine seed should be spread across the agar in Roux bottles, which should be incubated at 37°C until at least 80% sporulation is apparent by microscopic examination of aseptically extracted loopfuls (at least 72 hours). The growth is harvested with 10 ml per bottle of sterile deionised or distilled water and checked for purity. After washing three times in sterile deionised or distilled water with final suspension, also in sterile deionised or distilled water, sterilised lyophilisation stabiliser is added and the suspension is dispensed into lyophilisation vials and freeze-dried.

Attenuated vaccine strains can gradually lose their antigenicity over repeated subculturing conditions. Therefore, it is recommended that master seed lots be made in bulk and kept within three passages from the original seed culture. A large number of master seed stocks should be prepared.

ii) Preparation and testing of the working seed

Reconstitute a vial of seed stock and inoculate several slants (approximately 10 ml) of sporulation (casein digest) agar. Incubate at 37°C for 72 hours and store in a refrigerator. Test the slants for purity by culture on to nutrient agar plates and in nutrient broth (0.1 ml in 100 ml of nutrient broth). The latter should be subcultured on to nutrient agar after incubation at 37°C for 7 days and should be a pure culture of *B. anthracis*. A sample of the broth culture should also be checked for lack of motility.

Volumes of seed needed for a production run should be calculated on the basis of harvesting the spores from each slant with 10 ml of sterile deionised or distilled water and using this to inoculate five Roux bottles.

iii) Preparation of vaccine concentrate

Roux bottles with casein digest agar are prepared as for the master seed in Section C.2.2.1.i above. One Roux bottle can be expected to yield about 2000 doses of vaccine. Each Roux bottle is inoculated with 2 ml of working seed suspension and incubated at 37°C with porous plugs for several days until small loopfuls of culture from randomly selected bottles show at least 90% of the organisms to be in sporulated forms when examined in wet mounts by phase contrast (phase bright spores) or following staining for spores. The growth from each

1 UK Health Security Agency, Microbiology Services, Porton Down, Salisbury SP4 0JG, UK (www.culturecollections.org.uk/)

bottle is then harvested with 20 ml of physiological saline. Tests for contaminants should be carried out by subculture to nutrient agar plates and inoculation of 100 ml nutrient broth with 0.1 ml of harvested spores followed by subculture to nutrient agar after 7 days at 37°C and by tests for motility. Acceptable harvests (i.e. those showing no evidence of contaminants) are pooled.

iv) Glycerination

Twice the volume of sterile, pure, neutral glycerol should be added to the bulk pool of vaccine concentrate. Saponin (0.1% final concentration) may also be added at this point if it is to be included as an adjuvant. Mix thoroughly (the inclusion of sterilised glass beads may be helpful). Carry out a purity test and hold for 3 weeks at ambient temperature to allow lysis of any vegetative bacteria, determine the viable spore count and store under refrigeration thereafter.

v) Determining titre and dilution for use

The number of culturable spores in the product is then calculated by spreading tenfold dilutions on nutrient agar plates. The suspension is diluted so that the final bulk contains the number of culturable spores desired. The diluent should contain the same proportions of saline, glycerol and (if being included) saponin as present in the vaccine concentrate. The vaccine should contain a minimum of $2–10 \times 10^6$ culturable spores per dose for cattle, buffaloes and horses, and not less than $1–5 \times 10^6$ culturable spores per dose for sheep, goats and pigs.

vi) Filling the containers

Distribution of aliquots of vaccine into single and multidose containers is performed as outlined in WHO (1965). Basically, the final bulk is distributed to containers in an aseptic manner in an area not used for production, and any contamination or alteration of the product must be avoided. The vaccine may be lyophilised after distribution into appropriate dosage containers. Containers are sealed as soon as possible with a material that is not detrimental to the product and that is capable of maintaining a hermetic seal for the life of the vaccine.

2.3. Requirements for substrates and media

Please refer to Misra (1991) for detailed information on substrates and media used for anthrax vaccine production.

2.3.1. In-process controls

i) Purity of the seed lot

Purity tests consist of microscopic examination of stained smears with culture and motility tests as described in Section C.2.2.

ii) Safety of the seed lot

Not less than 5×10^9 culturable spores should be injected subcutaneously into each of three healthy, 1–2-year-old, unvaccinated sheep, which must survive an observation period of at least 10 days.

iii) Immunogenicity of the seed lot

At least 10 healthy guinea-pigs, 300–500 g in weight should be inoculated with 5×10^6 viable spores and observed for 21 days. At least 80% of the animals should survive. The immunised animals, together with three unimmunised controls, should then be challenged with 10 median lethal doses (LD_{50}) of the strain 17 JB of *B. anthracis*. During a 10-day observation period, none of the immunised animals should succumb to the challenge while all the controls should die from anthrax. The test should be repeated if one of the immunised animals dies.

2.3.2. Final product batch tests

i) Sterility and purity

The vaccine is a live culture of *B. anthracis* spores; sterility does not apply, but the batches must be tested for freedom from contamination (see Chapter 1.1.9 *Tests for sterility and freedom from contamination of biological materials intended for veterinary use*).

ii) Safety

Safety testing is performed on two healthy sheep or goats and consists of inoculating subcutaneously twice the recommended vaccination dose. The animals are observed for 10 days. The final bulk passes the test if no systemic reactions develop and if not more than a transient oedema is observed at the injection site. If the test is carried out in sheep only, a progressive oedema indicates that the vaccine may be unsuitable for goats.

iii) Batch potency

Efficacy or immunogenicity is tested on the final bulk as follows: at least ten healthy 300–500 g guinea-pigs are inoculated with a sheep dose of the vaccine. The guinea-pigs are observed for 21 days, and at least 80% of the animals must survive the observation period. Surviving immunised guinea-pigs and three non-vaccinated controls are challenged with an appropriate dose of virulent *B. anthracis*. A recommended challenge is 200 LD_{50} of the Pasteur II strain (17JB). If, by 10 days after challenge, all vaccinated guinea-pigs survive and control animals die, the final bulk is deemed to be satisfactory. If any vaccinated animals die during the post-challenge observation period from a cause other than anthrax, and death is not associated with the vaccine, the test may be repeated.

2.4. Requirements for authorisation

2.4.1. Safety requirements

i) Target and non-target animal safety

The vaccine has been shown to cause disease in some goats and llamas; this may be related to the saponin adjuvant. The vaccine is not recommended for use in pregnant animals, nor in animals destined for slaughter within 2–3 weeks of vaccination. Local regulations may specify other time periods in some countries or regions, but there is no scientific reason for regarding meat from clinically healthy animals as unfit for human handling or consumption after a holding period of 2 weeks following vaccination. Concurrent administration of antibiotics to vaccinated animals is contraindicated as the antibiotic will interfere with the vaccine. Antibiotics should not be given for several days before and after vaccination.

Accidental human inoculation is treated by expressing as much of the inoculum as possible from the injection site and washing the wound thoroughly with soap and water. Medical attention should be sought if infection develops.

ii) Reversion–to-virulence for attenuated/live vaccines

The 34F2 strain of *B. anthracis* is known to be stable and cannot produce capsule *in vitro*.

iii) Environmental consideration

Leftover vaccine, empty vials, and equipment used for vaccinating are contaminated with the live spores and should be autoclaved, disinfected, or incinerated.

2.4.2. Efficacy requirements

i) For animal production

Not applicable.

ii) For control and eradication

The recommended dose for cattle and horses is a minimum of 2–10 × 10^6 culturable spores; for sheep, goats and pigs, it is 1–5 × 10^6 culturable spores. The vaccine should contain these

spores in an appropriate volume, e.g. 2×10^6/ml. Immunity should be good for at least 1 year and it is recommended that an annual booster be given. Horses may be slow to develop immunity following initial vaccination; some manufacturers therefore recommend a two-dose initial vaccination, administered 1 month apart, followed by a single annual booster.

Bacillus anthracis spores are stable in unlyophilised or lyophilised vaccine and preservatives are not required. Storage under refrigeration is recommended (4°C).

As there is no generally acceptable test for stability of anthrax vaccines, it is recommended that, in each filling lot, the number of culturable spores be determined before and after holding at an appropriate temperature for an appropriate period. There should be no evidence of a fall in the number of culturable spores.

3. Vaccines based on biotechnology

3.1. Vaccines available and their advantage

There are no vaccines based on biotechnology available for anthrax.

3.2. Special requirements for biotechnological vaccines, if any

Not applicable.

CHAPTER 3.1.2.

AUJESZKY'S DISEASE (INFECTION WITH AUJESZKY'S DISEASE VIRUS)

SUMMARY

Description and importance of the disease: *Aujeszky's disease, also known as pseudorabies, is caused by an alphaherpesvirus that infects the central nervous system and other organs, such as the respiratory tract, in a variety of mammals except humans and the tailless apes. It is associated primarily with suidae (pigs or wild boars), the natural host, which remain latently infected following clinical recovery (except piglets under 2 weeks of age, which die from encephalitis). The disease is controlled by containment of infected herds and by the use of vaccines and/or removal of latently infected animals.*

A diagnosis of Aujeszky's disease is established by detecting the agent (by virus isolation or polymerase chain reaction [PCR]), as well as by detecting a serological response in the live animal.

Identification of the agent: *Isolation of Aujeszky's disease virus can be made by inoculating a tissue homogenate, for example of brain and tonsil or material collected from the nose/throat, into a susceptible cell line such as porcine kidney (PK-15 or SK6), or primary or secondary kidney cells. The specificity of the cytopathic effect is verified by immunofluorescence, immunoperoxidase or neutralisation with specific antiserum. The viral DNA can also be identified using PCR; this can be accomplished using real-time PCR techniques.*

Serological tests: *Aujeszky's disease antibodies are demonstrated by virus neutralisation, latex agglutination or enzyme-linked immunosorbent assay (ELISA). A number of ELISA kits are commercially available world-wide. A WOAH International Standard Reference Serum defines the lower limit of sensitivity for routine testing by laboratories that undertake the serological diagnosis of Aujeszky's disease.*

It is possible to distinguish between antibodies resulting from natural infection and those from vaccination with gene-deleted vaccines.

Requirements for vaccines: *Vaccines should prevent or at least limit the excretion of virus from the infected pigs. Recombinant DNA-derived gene-deleted or naturally deleted live Aujeszky's disease virus vaccines, lack a specific glycoprotein (gG, gE, or gC), which enables the use of companion diagnostic tests to differentiate vaccinal antibodies from those resulting from natural infection.*

A. INTRODUCTION

Aujeszky's disease, also known as pseudorabies, is caused by *Suid herpesvirus 1* (SHV-1), a member of the subfamily *Alphaherpesvirinae* and the family *Herpesviridae.* The virus should be handled with appropriate biosafety and containment procedures as determined by biorisk analysis (see Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*). The virus infects the central nervous system and other organs, such as the respiratory tract, of a variety of mammals (such as dogs, cats, cattle, sheep, rabbits, foxes, minks, etc.) except humans and the tailless apes. It is associated primarily with pigs, the natural host, which remain latently infected following clinical recovery (except piglets under 2 weeks of age, which die from encephalitis). In consequence, the pig is the only species able to survive a productive infection and therefore, serves as the reservoir host. In pigs, the severity of clinical signs depends on the age of the pig, the route of infection, the virulence of the infecting strain and the immunological status of the animal. Young piglets are highly susceptible with mortality rates reaching 100% during the first 2 weeks of life.

These animals show signs of hyperthermia and severe neurological disorders: trembling, incoordination, ataxia, nystagmus to opisthotonos and severe epileptiform-like seizures. When pigs are older than 2 months (grower-finisher pigs), the respiratory forms become predominant with hyperthermia, anorexia, and mild to severe respiratory signs: rhinitis with sneezing and nasal discharge that may progress to pneumonia. The frequency of secondary bacterial infections is high, depending on the health status of the infected herd. In this group of pigs, the morbidity can reach 100%, but in cases of the absence of complicated secondary infections, mortality ranges from 1% to 2% (Pejsak & Truszczynski, 2006). Sows and boars primarily develop respiratory signs, but in pregnant sows, the virus can cross the placenta, infect and kill the fetuses, inducing abortion, return to oestrus, or stillborn fetuses. Virus may be found in the semen of infected boars (van Rijn *et al.,* 2004). In the other susceptible species, the disease is fatal, the predominant sign being intense pruritus causing the animal to gnaw or scratch part of the body, usually head or hind quarters, until great tissue destruction is caused. For that reason, the disease was named "mad-itch" in the past.

Focal necrotic and encephalomyelitis lesions occur in the cerebrum, cerebellum, adrenals and other viscera such as lungs, liver or spleen. In fetuses or very young piglets, white spots on liver are highly suggestive of their infection by the virus. Intranuclear lesions are frequently found in several tissues.

Aujeszky's disease is endemic in many parts of the world, but several countries have successfully completed eradication programmes, e.g. the United States of America, Canada, New Zealand and many Member States of the European Union.

The disease is controlled by containment of infected herds and by the use of vaccines or removal of latently infected animals (Pejsak & Truszczynski, 2006). Stamping out has been or is used in several countries usually when the infected farms are small or when the threat to neighbouring farms is very high in free countries.

Whereas isolation of the Aujeszky's disease virus or detection of the viral genome by the polymerase chain reaction (PCR) are used for diagnosis in the case of lethal forms of Aujeszky's disease or clinical disease in pigs, serological tests are required for diagnosis of latent infections and after the disappearance of the clinical signs. Affected animals except suids, do not live long enough to produce any marked serological response. Serological tests are the tests to be used to detect subclinically or latently infected pigs, especially in the case of qualification of the health status of the animals for international trade or other purposes.

B. DIAGNOSTIC TECHNIQUES

Table 1. Test methods available for the diagnosis of Aujeszky's disease and their purpose

Method	Purpose					
	Population freedom from infection	Individual animal freedom from infection prior to movement	Contribute to eradication policies	Confirmation of clinical cases	Prevalence of infection – surveillance	Immune status in individual animals or populations post-vaccination
Identification of the agent[(a)]						
Virus isolation	–	–	–	+++	–	–
Real-time PCR	–	+	+	+++	+	–
Detection of immune response						
Latex agglutination	+++	+++	+++	+	+++	+++
ELISA	+++	+++	+++	+	+++	+++
VN	+	+	+	+	+	+++

Key: +++ = recommended for this purpose; ++ recommended but has limitations;
+ = suitable in very limited circumstances; – = not appropriate for this purpose.
PCR = polymerase chain reaction; ELISA = enzyme-linked immunosorbent assay; VN = virus neutralisation.
[(a)]A combination of agent identification methods applied on the same clinical sample is recommended.

1. Identification of the agent

1.1. Virus isolation

The diagnosis of Aujeszky's disease can be confirmed by isolating the virus from the oro-pharyngeal fluid, nasal fluid (swabs) or tonsil swabs from living pigs, or from samples from dead pigs or following the presentation of clinical signs such as encephalitis in herbivores or carnivores. For post-mortem isolation of SHV-1, samples of brain, tonsil, and lung are the preferred specimens. In cattle, infection is usually characterised by a pruritus, in which case a sample of the corresponding section of the spinal cord may be required in order to isolate the virus. In latently infected pigs, the trigeminal ganglia is the most consistent site for virus isolation, although latent virus is usually non-infective unless reactivated, making it difficult to recover in culture.

Tissue samples are homogenised in normal saline or cell culture medium with antibiotics. The method used should be suitable for the subsequent diagnostic test. The amount of tissue homogenised should take into account a possible non-homogeneous distribution of the virus. A tissue homogenate of approximately 10% is recommended. The resulting suspension is clarified by low speed centrifugation, e.g. at 900 ***g*** for 10 minutes. The supernatant fluid is used to inoculate any sensitive cell culture system. Numerous types of cell line or primary cell cultures are sensitive to SHV-1, but a porcine kidney cell line (PK-15 or SK6) is generally employed. The overlay medium for the cultures should contain antibiotics (such as: 200 IU/ml penicillin; 100 μg/ml streptomycin; 100 μg/ml polymyxin; and 3 μg/ml fungizone).

SHV-1 induces a cytopathic effect (CPE) that usually appears within 24–72 hours, but cell cultures may be incubated for 5–7 days. The monolayer develops accumulations of birefringent cells, followed by complete detachment of the cell sheet. Syncytia also develop, the appearance and size of which are variable. In the absence of any obvious CPE, it is advisable to make one blind passage into further cultures. Additional evidence may be obtained by staining infected cover-slip cultures with haematoxylin and eosin to demonstrate the characteristic herpesviral acidophilic intranuclear inclusions with margination of the chromatin. Virus identity should be confirmed by immunofluorescence, immunoperoxidase, neutralisation using specific antiserum following the method described in Section B.2.1. or by PCR.

The isolation of SHV-1 makes it possible to confirm Aujeszky's disease, but failure to isolate does not guarantee freedom from infection.

1.2. Identification of virus by the polymerase chain reaction

The PCR can be used to identify SHV-1 genomes in secretions or organ samples. Many individual laboratories have established effective protocols, but there is as yet no internationally agreed standardised approach.

The PCR is based on the selective amplification of a specific part of the genome using two primers located at each end of the selected sequence. In a first step, the complete DNA may be isolated using standard procedures (e.g. proteinase K digestion and phenol–chloroform extraction) or commercially available DNA extraction kits. Using cycles of DNA denaturation to give single-stranded DNA templates, hybridisation of the primers, and synthesis of complementary sequences using a thermostable DNA polymerase, the target sequence can be amplified up to 10^6-fold. The primers must be designed to amplify a sequence conserved among SHV-1 strains, for example parts of the gB or gD genes that code for essential glycoproteins have been used (Mengeling *et al*., 1992; Van Rijn *et al*., 2004; Yoon *et al*., 2006). Real-time PCRs have been developed that can differentiate gE-deleted vaccine viruses from wild-type virus based on the specific detection of gB and gE genes (Ma *et al*., 2008; Wernike *et al*., 2014).

The amplified product may be identified from its molecular weight as determined by migration in agarose gel, with further confirmation where possible by sequencing the amplified product. More recent techniques include the use of fluorescent probes linked to an exonuclease action and real-time monitoring of the evolution of product, enabling simultaneous amplification and confirmation of the template DNA thus increasing the rapidity and specificity of the PCR assays.

In all cases, the main advantage of PCR, when compared with conventional virus isolation techniques, is its rapidity; with the most modern equipment, the entire process of identification and confirmation can be completed within one day. However, because of the nature of the test, many precautions need to be taken to avoid contamination of samples with extraneous DNA from previous tests or from general environmental contamination in the laboratory (see Chapter 1.1.9 *Tests for sterility and freedom from contamination of biological materials intended for veterinary use*). This may limit the value of the test for many laboratories unless care is taken to avoid DNA carry-over contamination. The use of an internal control is recommended so as to avoid false-negative results by ensuring adequate efficiency of DNA extraction and confirming the absence of PCR inhibitors in each sample. In practice, different systems can be used for detection of endogenous or exogenous genes (Hoffman *et al.,* 2009). Kits for the test are commercially available (Pol *et al.,* 2013).

2. Serological tests

Virus neutralisation (VN) has been recognised as the reference method for serology (Moennig *et al*., 1982), but for general diagnostic purposes it has been widely replaced by the enzyme-linked immunosorbent assay (ELISA) because of its suitability for large-scale testing (Moennig *et al*., 1982). The tests can be performed on a variety of matrices (e.g. serum, whole blood, milk, muscular exudates, and filter paper), but the preferred matrix is serum.

A latex agglutination test has also been developed, and can be used for screening for antibodies. Kits for the test are commercially available (Schoenbaum *et al*., 1990).

Serological tests are carried out only for suids, as other animals (herbivores and carnivores) die too quickly to produce antibodies. In free areas where pigs are not vaccinated, an active epidemiological survey can be carried out using ELISA gB or gE or latex agglutination kits. As antibodies can be detected between 7 and 10 days post-infection, these serological tools can also be used to confirm infection in pigs in the case of a suspected outbreak. In area where pigs are vaccinated with gE deleted vaccines, the ELISA gE kits permit the differentiation between infected and vaccinated pigs (DIVA), but to assess the level of immunity induced by vaccination, gB ELISA, latex agglutination kits or viral neutralisation should be used.

Any serological technique used should be sufficiently sensitive to give a positive result with the WOAH International Standard Reference Serum or a calibrated secondary serum. Reference serum can be obtained from the WOAH Reference Laboratory for Aujeszky's Disease in France (see Table given in Part 4 of this *Terrestrial Manual*). For international trade purposes, the test should be sensitive enough to detect the standard serum diluted 1/2. To authorise pig movement from an area where deleted gE vaccines are used to a free area, serological assays should be able to detect at least the dilution of 1/8 for ELISA gE of the WOAH International Standard Reference Serum as prescribed by the European Commission (2008).

2.1. Virus neutralisation

VN in cell culture can be performed in several ways, which vary according to the length of incubation of the virus/serum mixtures (e.g. 1 hour at 37°C or 24 hours at 4°C) and the presence or absence of complement. Most laboratories use a reaction period of 1 hour at 37°C in the absence of complement, because this is easy and rapid. However, the sensitivity can be improved by increasing the incubation period to 24 hours at 4°C, which facilitates the detection of antibody levels 10–15 times lower than in the 1-hour method. For international trade purposes, the test method should be validated as being sensitive enough to detect the WOAH Standard Reference Serum diluted 1/2.

VN cannot be used to differentiate antibodies of vaccinal origin from those caused by natural infection. It is one of the two tests available that complies with the requirement in the WOAH *Terrestrial Animal Health Code* chapter when it refers to "a diagnostic test to the whole virus".

i) Cells

Cells susceptible to infection with SHV-1 are used; they may be cell lines (e.g. PK-15, SK6, MDBK), or primary or secondary cell cultures (e.g. porcine kidney).

ii) Cell culture medium

The medium depends on the type of cells. For example, the medium for PK-15 cells is Eagle's minimal essential medium (MEM) + 10% fetal bovine serum and antibiotics (100 IU/ml penicillin and 100 μg/ml streptomycin or, alternatively, 50 μg/ml gentamycin).

iii) Maintenance of the cells

The cells are cultured in cell culture vessels of, for example, 75 cm^2. They are trypsinised once or twice per week. For weekly trypsinisation, the cells are usually cultured in 50 ml of medium, with a multiplication rate of 5. For two trypsinisations a week, the cells are cultured in 30 ml of medium, with a multiplication rate of 3.

For trypsinisation, the growth medium is removed once the cell sheet is complete. The cell sheet is washed with about 5 ml of recently thawed trypsin/ethylene diamine tetra-acetic acid (EDTA) (0.25%) in an isotonic buffer. The washing fluid is discarded and the preparation is washed again, retaining only a few drops of trypsin. The container is placed in an incubator at 37°C for 5–10 minutes until the cells have become detached. Once the sheet is detached and the cells are well separated, for twice weekly passage they are suspended in 90 ml of growth medium, and this suspension is distributed into three 75 cm^2 cell culture vessels. For weekly trypsinisation the cells are suspended in 150 ml of growth medium and the suspension distributed into five 75 cm^2 cell culture bottles.

iv) Virus

A suitable strain of SHV-1, such as the Kojnok strain or the NIA-3 strain, is stored at a temperature of –65°C or below, or in freeze-dried form at 4°C.

v) Preparation of stock virus suspension

The culture fluid is removed from a cell culture vessel containing a complete cell sheet. About 1 ml of stock virus suspension of known titre (about 10^7 $TCID_{50}$/ml [50% tissue culture infective dose]) is added, and the vessel is incubated at 37°C±2°C for 1 hour. 30 ml of culture medium is added and the vessel is again incubated at 37°C±2°C. The vessel is examined frequently until there is about 75% cell destruction (after about 36–48 hours). It is then frozen at a temperature of –65°C or lower to disrupt the cells.

The vessel is then thawed and shaken vigorously. Medium is collected and centrifuged at 1500 ***g*** for 15 minutes. The supernatant fluid is divided into portions (of about 0.5 ml) in small tubes that are labelled (date and virus reference) before being stored at a temperature of –65°C or lower until required.

vi) Titration of the stock virus suspension

Titration of the stock suspension is performed by the method of Reed & Muench or that of Kärber, and the titre is expressed per 50 μl and per ml.

The VN test requires an internal quality control serum with a known titre of neutralising antibody to SHV-1 (it can be calibrated against an international standard serum or a secondary standard prepared from that serum), and a negative control serum (from a specific antibody free pig, e.g. from an official Aujeszky's disease free herd). The test sera themselves should be of good quality, clearly labelled, of known provenance with clinical history, stored in refrigeration at all times, free from fungal or bacterial contamination, non-haemolysed and of sufficient quantity. Serum should be separated from the coagulum without delay, thereby preventing toxicity.

There are qualitative and quantitative procedures for VN, both of which are described below.

2.1.1. Qualitative virus neutralisation technique

i) Complement in the serum samples is destroyed by heating in a water bath at 56–59°C for 30 minutes.

ii) Each undiluted serum sample is placed in two to three wells, at 50 μl per well, of a 96-well cell-culture grade microtitre plate. Each serum can also be diluted 1/2 in the MEM, before being placed in two other wells.

iii) 50 µl of virus suspension containing 100 $TCID_{50}$ (or 2×10^3 $TCID_{50}$/ml), obtained by diluting stock virus suspension of known titre with MEM, is added to each well.

iv) The plate is gently shaken and placed in an incubator for 1 hour at 37°C (±2°C) (5% CO_2 optional).

v) 150 µl of cell suspension containing about 150,000 cells/ml is added to each well.

vi) The plate is covered (for incubation in CO_2), or a plastic sheet is sealed carefully around the edges of the plate (for incubation in air). The plate is shaken lightly to obtain an even distribution of cells at the bottom of the wells, and placed in the incubator at 37°C (±2°C) (CO_2 optional) for 3–5 days.

vii) *Controls:* Each set of plates must include the following controls:

a) Virus control

This is to verify the amount of virus actually used for the test. The virus dose used for VN (target titre 100 $TCID_{50}$/50 µl) is diluted with MEM at 1/10, 1/100 and 1/1000. Of each dilution, 50 µl is placed in at least four wells, to which 50 µl of medium is added before the wells are incubated for 1 hour at 37°C (±2°C). The cell suspension is added in the same way as for the sera under test.

b) Cell control

150 µl cell suspension and 100 µl MEM are placed in each of at least four wells.

c) Positive serum control

A serum of known SHV-1 neutralising antibody titre is used. Five dilutions are prepared in the same way as for the sera under test: a dilution corresponding to the serum titre, two-fold and four-fold dilutions, and 1/2 and 1/4 dilutions (equivalent to T, T/2, T/4, 2T and 4T, where T is the serum titre, i.e. undiluted serum for the qualitative test). Add 50 µl of virus suspension containing 100 $TCID_{50}$/50 µl to 50 µl of positive control sample dilutions. The cells are incubated and the cell suspension is added in the same way as for the sera under test.

d) Serum control

This is to verify the absence of a toxic effect of the sera on the cells. Wells containing 50 µl of each serum are incubated for 1 hour at 37°C in the presence of 50 µl of medium. Then, 150 µl of cell suspension is added in the same way as for the sera under test.

e) Negative serum control

This is done in the same way as for sera under test.

viii) *Reading the results:* An inverted-image microscope (×100) is used to examine the wells for toxic effects and CPEs after 3 to 5 days. The controls must give the following results if the tests are to be considered valid:

a) Virus control

The titre of the viral suspension should be between 30 and 300 $TCID_{50}$/50 µl.

b) Cell control

The cell sheet must be intact.

c) Positive serum control

The titre obtained must be equal to the predicted titre, within one dilution.

d) Serum control

Examination for a CPE should take into account a possible toxic effect on cells.

e) Negative serum control

A CPE should be present.

ix) For the sera under test if distributed in three wells, the following results may be seen:

a) presence of a CPE in three wells = negative result;

b) absence of a CPE in three wells on day 3 = positive result;

c) presence of a CPE in one well but not in the others = inconclusive result, test must be repeated;

d) small plaques indicating a CPE on day 3 = inconclusive result, test must be repeated;

e) toxicity in serum control and test wells = unreadable result, test must be repeated. (NB replacement of medium with fresh medium after 16 hours' incubation will reduce the toxicity without affecting the titre of specific antibody.) Plates can be read until day 5 of incubation.

f) If the serum was initially diluted 1/2 and distributed in two wells, it is considered positive if CPE is absent in one of the two wells, and it is highly recommended to retest using the quantitative technique. Diluting the serum to 1/2 can prevent the toxicity effect of the tested sera.

x) *Interpretation of the results:* This test is capable of detecting the presence or absence of neutralising antibody to SHV-1. It is incapable of distinguishing vaccinated animals from infected animals.

The technique described (VN for 1 hour at 37°C) can give false-negative and false-positive results. The sensitivity can be increased (leading to fewer false negatives) by adopting a method based on neutralisation involving 24 hours of contact between virus and serum at 4°C, before the addition of cells.

A qualitative technique such as this one, which employs undiluted serum samples (1/2 final dilution), can give a false-positive result in certain cases due to nonspecific neutralisation of the virus. This problem can be addressed by carrying out a confirmatory test using the quantitative technique (see Section B.2.1.2 below).

Samples giving inconclusive results may be tested by an alternative technique with better sensitivity such as an ELISA or the animal should be re-bled to confirm status.

2.1.2. Quantitative virus neutralisation technique

The quantitative VN technique is similar to the qualitative procedure, but each serum is used both undiluted and in a series of dilutions. Depending on the desired precision, the purpose of testing and the expected titre, two wells are used for each dilution of serum, and a range of dilutions appropriate for the purpose. The procedure below describes the test for an initial maximum dilution of 1/16. It is possible to reach higher titres using more wells (e.g. A1 to A12 for 1/256 dilution).

i) Complement in the serum samples is destroyed by heating in a water bath at 56–59°C for 30 minutes.

ii) 75 µl of MEM is added to well A2 and 50 µl of MEM is added to wells A1, and A3 to A6 of a 96-well cell-culture grade microtitre plate and continued for comparable wells in rows B, C, etc., for additional serum samples.

iii) 75 µl of undiluted serum sample is added to well A2, and continued for wells in rows B, C, etc., with other serum samples.

iv) Using a multichannel pipette, the contents of wells in column 2 are mixed, then 50 µl is transferred to column 1 and 3, and so on to column 6 or further to a predetermined row, using the same nozzles. The 50 µl portions remaining after the last row are discarded.

v) 50 µl of virus suspension containing 100 $TCID_{50}$ (or 2×10^3 $TCID_{50}$/ml), obtained by diluting stock virus suspension of known titre with MEM, is added to each well in columns 2 to 6. No virus is added to wells in column 1, this is a control column of serum samples.

vi) The plate is shaken and placed in an incubator for 1 hour at 37°C (±2°C) (5% CO_2 optional).

vii) 150 µl of cell suspension containing about 150,000 cells/ml is added to each well.

viii) The plate is covered (for incubation in CO_2), or a plastic sheet is sealed carefully around the edges of the plate (for incubation in air). The plate is shaken lightly to obtain an even distribution of cells at the bottom of the wells, and placed in the incubator at 37°C (±2°C) (CO_2 optional) for 3–5 days.

ix) Controls are set up as described for the qualitative technique.

x) *Reading the results:* The neutralising titre of a serum is expressed by the denominator of the highest initial dilution that brings about complete neutralisation of the CPE of the virus in 50% of the wells. Neutralisation at any dilution (even undiluted, equivalent to a final dilution of 1/2) is considered to be positive. If the serum shows neutralisation only when undiluted (with growth of virus and CPE at the 1/2 and subsequent dilutions), it would be advisable to apply alternative tests (ELISA or latex agglutination) to provide confirmation of the result, or to request another sampling of the animal, at least 8 days after the first.

2.2. Enzyme-linked immunosorbent assay

The sensitivity of the ELISA is generally superior to that of the VN test using 1-hour neutralisation without complement. Some weak positive sera are more readily detected by VN tests using 24-hour neutralisation, while others are more readily detectable by ELISA.

ELISA kits, which are available commercially, use indirect or competitive techniques for detecting antibodies. They differ in their mode of preparation of antigen, conjugate, or substrate, in the period of incubation and in the interpretation of the results. Their general advantage is that they enable the rapid processing of large numbers of samples. This can also be automated and the results analysed by computer. Some of these kits make it possible to differentiate between vaccinated and naturally infected animals when used with a 'matching' vaccine (Eloit et al., 1989; Van Oirschot et al., 1986). Alternatively, non-commercial ELISA protocols may be adopted (Toma & Eloit, 1986) provided they are shown to detect the WOAH International Standard Reference Serum as positive at a dilution of 1/2 (the minimum sensitivity for international trade purposes). It is recommended to use a kit or in-house assay that has been validated to this standard or a secondary standard prepared against the International Reference Standard by external quality control tests by an independent laboratory. A suitable test protocol for whole virus antibodies is presented below (Toma & Eloit, 1986).

2.2.1. Preparation of antigen

i) A cell line sensitive to SHV-1, such as PK-15 or fetal pig testis, is used. It must be free from extraneous viruses, such as bovine viral diarrhoea virus. The cells should be split and seeded into fresh 75 cm^2 flasks the day before inoculation. A suitable medium such as MEM, without serum, is used to overlay the cultures.

ii) Virus inoculated, and control uninoculated flasks are processed in parallel throughout. A suitable well characterised strain of SHV-1 is used, e.g. Kojnock strain. When a confluent cell monolayer has developed (approximately 24 hours after seeding), it is inoculated with 10^8 $TCID_{50}$ SHV-1 in 5 ml medium; and 5 ml medium (without virus) is placed in control flasks. The cultures are left for adsorption for 30 minutes at 37°C, and then overlaid with 20 ml medium.

iii) When CPE is just beginning, the supernatant medium is discarded and 4 ml KCl (4 mM solution) and glass beads are added. The flasks are shaken gently to detach cells.

iv) Cells are washed by centrifuging three times at 770 ***g*** in 4 mM KCl. The pellet is resuspended in 4 mM KCl with 0.2% Triton X-100 (1 ml per flask) by applying 60 strokes with a glass homogeniser

v) The cell homogenate is layered on to 0.25 mM sucrose in 4 mM KCl and centrifuged for 10 minutes at 770 ***g***.

vi) The pellet is resuspended in antigen-diluting buffer, pH 9.6 (0.1 M Tris, 2 mM EDTA, 0.15 mM NaCl) at 1/50 the volume of the original culture medium. It may then be stored in small aliquots at –70°C. Antigen is stable in this form for 2 years.

2.2.2. Coating microtitre plates

i) Virus antigen and control (no virus) antigen are diluted in diluting buffer, pH 9.6 (see above) to a dilution predetermined in chequerboard titrations.

ii) 200 µl of antigen is dispensed into each well of 96-well ELISA-grade plates, coating alternate rows with SHV-1 positive and control antigen. Incubation is for 18 hours at 4°C.

iii) The plates are washed three times with washing solution (Tween 20, 0.5 ml/litre).

iv) Coated plates are stored at –20°C or –70°C. They are stable for several months.

2.2.3. Test procedure

i) Test serum samples are diluted 1/30 in PBS/Tween buffer, pH 7.2 (137 mM NaCl, 9.5 mM phosphate buffer, 0.5 ml/litre Tween 20).

ii) Diluted samples are added to virus and control antigen coated wells, and incubated at 37°C for 30 minutes.

iii) The plates are washed three times with washing solution (0.5 ml/litre Tween 20).

iv) Protein A/peroxidase conjugate is added to all wells at a predetermined dilution in PBS/Tween buffer, pH 7.2 (see above), with added bovine serum albumen fraction V (10 g/litre), and the plates are incubated at 37°C for 30 minutes.

v) The plates are washed three times with washing solution (0.5 ml/litre Tween 20).

vi) A suitable chromogen/substrate mixture, such as tetra methyl benzidine (TMB)/hydrogen peroxide, is added to each plate.

vii) The reaction is stopped with 2 M sulphuric acid. The absorbance is read at 492 nm.

The test must be fully validated using known positive and negative sera, and calibrated against the WOAH International Standard Reference Serum. It is highly recommended to carry out a batch control for each batch of the test, to determine sensitivity and specificity in relation to the original validation criteria (criteria to accept or refuse the batch have to be set). For routine analysis, all tests must include positive and negative internal controls, including at least one weak positive sample that, when diluted at the appropriate dilution for the test, has equivalent activity to a 1/2 dilution of the WOAH International Standard Reference Serum. Internal controls are also used to monitor the sensitivity, specificity and reproducibility of the test over time. For further details see Toma & Eloit, 1986 and Chapter 1.1.6 *Validation of diagnostic assays for infectious diseases of terrestrial animals*. Commercial ELISA kits also have to be validated in the setting in which they are going to be used.

As well as testing sera, the ELISA can be adapted to test pools of sera, filter paper disks that have been moistened with a small quantity of blood obtained by puncturing a superficial vein (Banks, 1985; Toma *et al.,* 1986), or muscle exudates (Le Potier *et al.,* 1998). These techniques make it convenient to collect blood samples from large numbers of pigs (Vannier *et al.,* 2007). The disks are air-dried before shipment to the laboratory. The (analytical) sensitivity may be lower than for a standard ELISA due to the type of sample or unavoidable dilution of the sample. Use of an adapted ELISA is therefore more appropriate for testing at the population level rather than for individual testing (e.g. prior to animal movement), unless a validation study has shown a comparable (analytical) sensitivity to the standard ELISA.

Requirements for the detection of gE antibodies by ELISA in pigs destined for slaughter that are to be introduced into zones free from Aujeszky's disease have been defined by several control authorities. For example, in the European Union, ELISA gE kits must be able to detect activity at least equivalent to a 1/8 dilution of the WOAH International Standard Reference Serum (European Commission, 2008). The WOAH *Terrestrial Animal Health Code* specifies circumstances in which gE-specific tests may be used. The gE ELISAs can also be adapted to test blood on filter paper disks depending on its sensitivity.

C. REQUIREMENTS FOR VACCINES

1. Background

1.1. Rationale and intended use of the product

Aujeszky's disease may be controlled by the use of vaccines containing either modified live or inactivated virus antigens. In addition, these conventional vaccines have been supplemented by recombinant DNA-derived gene-deleted or naturally deleted live SHV-1 vaccines. These vaccines, referred to as marker or DIVA-vaccines, are made with a virus that lacks a specific glycoprotein (most commonly gE-, although gG- or gC-deleted vaccines have also been described, as have vaccines with multiple deletions[1]). These gene-deleted DIVA-vaccines have the advantage over conventional whole virus vaccines that it is possible to distinguish infected animals from non-infected vaccinated animals. This is done by testing for the antibodies directed against the protein coded for by the deleted gene, which will be absent in non-infected DIVA-vaccinated pigs but present in field-infected pigs. Therefore, in countries with infected pigs, where the eradication of Aujeszky's disease is planned, these DIVA-vaccines are the vaccines of choice (Pensaert *et al*., 2004). Standards applicable to the manufacture of live and inactivated virus vaccines are described. For DIVA-vaccines, the tests should include demonstrable absence of a serological response in vaccinated pigs to the protein coded for by the deleted gene, and in addition a demonstrable response to the same protein in vaccinated pigs that become infected by field virus.

Other vaccines are inactivated and constituted of adjuvanted, viral subunit of purified and concentrated immunogenic glycoproteins (except the gE) allowing differentiation of vaccinated from infected pigs.

Guidelines for the production of veterinary vaccines are given in Chapter 1.1.8 *Principles of veterinary vaccine production*. The guidelines given here and in chapter 1.1.8 are intended to be general in nature and may be supplemented by national and regional requirements.

2. Outline of production and minimum requirements for conventional vaccines

2.1. Characteristics of the seed

2.1.1. Biological characteristics

Vaccines are made using a seed-lot system in which a master seed virus (MSV) is prepared from a suitable strain of Aujeszky's disease virus. A number of strains are used for vaccine manufacture. The antigen in an inactivated vaccine can be one of a number of wild-type strains, or the naturally deleted Bucharest virus. Modified live conventional vaccines use numerous strains, such as Bartha or are derived from Aujeszky's original isolate or from other field isolates, such as the NIA-3 strain (Marchioli *et al*., 1987; McFerran & Dow, 1975; Van Oirschot *et al*., 1990; Visser & Lutticken, 1988).

It is recommended that for differentiating between infected and vaccinated animals, deleted strains should be used.

A virus identity test (using either a fluorescent antibody test, neutralisation test, [constant serum/decreasing virus method], or any other suitable identity test) must be conducted on the MSV.

2.1.2. Quality criteria (sterility, purity, freedom from extraneous agents)

Most of the cell lines used to propagate SHV-1 are continuous lines, such as the PK-15 line. A master cell stock (MCS) is established at a specified passage level. The MCS and the highest passage level (MCS × n) intended for use in the preparation of a biological product is specified in

1 The nomenclature for the genes changed several years ago, but the old designation is still in the literature. The old and the new nomenclature is: gII = gB; gIII = gC; gp50 = gD; gI = gE; gX = gG; gp63 = gI. Note that some commercial serological kits may still be named by the old nomenclature.

an Outline of Production. Both MCS and MCS × n are monitored by a variety of procedures to characterise the cell line and to ensure freedom from adventitious agents. The extraneous agents to be detected are generally defined in monographs or guidelines (e.g. European Pharmacopoeia, US Code of Federal Regulations, EU guidelines, etc.). In general, the type of agents to be looked for is founded on a risk analysis depending on the history of the viral strain and cells on which the vaccinal strain was isolated and on which it is cultivated. The MCS must be monitored for species of origin. A minimum of 50 mitotic cells should be examined at both the MCS and MCS × n passage levels. The modal number in the MCS × n must not exceed 15% of the modal number of the MCS. Any marker chromosomes in the MCS must also be present in the highest cell passage.

If there is evidence that the cell line may induce malignancies in the species for which the product is intended, the cell line is tested for tumorgenicity and oncogenicity.

Both the MSV and the MCS must be shown to be free from mycoplasma, bacteria, fungi, cytopathogenic or haemadsorbing viruses, porcine parvovirus, cytopathic and noncytopathic ovine and bovine pestiviruses and other extraneous agents, such as circovirus, as determined by culturing and by fluorescent antibody procedures or others, such as PCR.

2.2. Method of manufacture

2.2.1. Procedure

Only MSV that has been established as pure, safe and immunogenic may be used as seed for a vaccine product. Cells from the MCS are propagated in a variety of growth media. All batches of vaccine must be from the first to the twentieth passage of MCS.

2.2.2. In-process controls

It is necessary to carry out tests at each critical step of the manufacturing process. The control tests are also carried out on intermediate products with a view to verifying the consistency of the production process and the final product.

2.2.3. Final product batch tests

It is essential to differentiate the tests that are carried out on a routine basis to release batches of final product from those that are performed to define the biological properties of a vaccine. The trials carried out for batch release are not the same as the ones carried out once only to determine the safety and efficacy of a vaccine. The batch release controls are always short-term trials, as inexpensive as possible, and not always carried out in pigs. Their purpose is mainly to attest the reproducibility of the quality of the finished product, which has to be in compliance with the quality initially defined in the application for marketing authorisation.

i) Sterility and purity

Tests must be carried out for sterility and freedom from contamination (see chapter 1.1.9 and Section C.2.1.2 of this chapter).

Each batch of SHV-1 vaccines must be tested for freedom from extraneous viruses. Using a minimum amount of a monospecific antiserum, the live vaccinal strain is neutralised and inoculated into cell cultures known to be sensitive to viruses pathogenic for pigs. No CPE and no haemadsorbing agents should be detected. The vaccines have to be free from pestiviruses.

ii) Inactivation

For inactivated vaccines, inactivation must be checked using two passages in the same type of cell culture as used in the production of the vaccine. Tests can be carried out by vaccinating susceptible animals such as rabbits.

iii) Identity

Where necessary, a specific test for virus identification should be carried out.

iv) Safety

Safety tests in target animals are not required by many regulatory authorities for the release of each batch. Where required, standard procedures should be statistically relevant and target the smallest number of animals required for the relevant regulatory approval.

v) Batch potency

The potency of the vaccine must be demonstrated using a suitable method, the results of which have to be correlated with the efficacy tests described previously.

In this kind of test, the most difficult point is to determine an acceptability threshold for using or rejecting the batch according to the results that are obtained.

Virus content tests should be carried out using each of at least three containers. The virus titre of the vaccine must be determined and must normally not be higher than 1/10 of the dose at which the vaccine has been shown to be safe, and not lower than the minimum release titre.

vi) Preservatives

If no preservative is included in the final product, the manufacturer must demonstrate that the product remains acceptable for its recommended period of use after opening the vial.

The efficacy of preservatives in multidose containers must be demonstrated. The concentration of the preservative in the final filled vaccine and its persistence throughout shelf life must be checked.

vii) Precautions (hazards)

All information about possible adverse reactions induced by the vaccine must be indicated. Any putative risk for human health if the user is accidentally given a small quantity of the product has to be indicated. The manufacturer should indicate all the conditions of use of the vaccine: mixing, reconstitution, storage, asepsis, length of needle, route of administration and health status of the vaccinated animals.

2.2.4. Stability tests

Tests have to be carried out to verify the shelf life proposed by the manufacturer. These tests must always be real-time studies; they must be carried out on a sufficient number of batches (at least three) produced according to the described production process and on products stored in the final container, and normally include biological and physicochemical stability tests. The manufacturer has to provide the results of analyses that support the proposed shelf life under all proposed storage conditions. Usually, the proposed shelf life corresponds to the period for which the product is considered to be stable minus 3 months.

2.3. Requirements for authorisation

2.3.1. Safety requirements

Local and general reactions must be examined. When a live vaccine is used, it is necessary to differentiate the exact safety properties of the vaccinal strain from those of the finished product if this includes an adjuvant.

Objective and quantifiable criteria to detect and measure adverse reactions should be used; these would include temperature changes, weight gain, litter size, reproductive performance, etc., of vaccinated and control groups. The tests must be performed by administering the vaccine to the pigs in the recommended dose and by each recommended route of administration.

In general, safety is tested initially under experimental conditions, following the requirements of the WOAH *Terrestrial Animal Health Code,* Chapter 7.8 *Use of animals in research and education*.

When the results of these preliminary tests are known, it is necessary to increase the number of animals vaccinated in order to evaluate the safety of the vaccine under practical conditions.

i) Laboratory testing

All tests must be carried out on pigs that do not have antibodies against Aujeszky's disease virus or against a subunit of the virus.

a) General effects

1. Live vaccines

Intranasal tests and vaccination of 3- to 5-day-old piglets are very useful for ascertaining the degree of safety of a strain. At least five piglets should be used.

It is also essential to assess the properties of a vaccine, especially live ones, in the target animals under normal conditions of use and at the youngest age intended for vaccination, e.g. fattening pigs, which are generally vaccinated when they are between 9 and 12 weeks old, and pregnant sows when this use of the vaccine is claimed by the manufacturer and is authorised. No clinical signs, including significant thermal reactions (data have to be recorded before vaccination and on a schedule such as 6 hours, 24 hours and 48 hours later, then on a daily basis during the observation period), should be observed after vaccination. These assays have to be performed on at least ten vaccinated pigs, with five unvaccinated pigs as controls.

Reversion to virulence following serial passage must be examined. Primary vaccination is done by the intranasal route. Series of at least four passages in piglets are made. No fewer than two fully susceptible animals must be used for each passage.

The object of these assays is to test the genetic stability of live vaccine strains. The tests appear to be less necessary when a genetically modified live strain is concerned, especially if it is produced by gene deletion.

It is recommended to test for possible excretion of the vaccine strain. For this purpose, no fewer than 14 piglets, 3–4 weeks old each receive one dose of vaccine by the recommended route and at the recommended site (except for vaccines administered by the intranasal route). Four unvaccinated piglets are kept as controls. Suitably sensitive tests for the virus are carried out individually on the nasal and/or oral secretions of vaccinated and in-contact pigs as follows: nasal and oral swabs are collected daily from 1 day before vaccination to 10 days after vaccination. Vaccine strains that are isolated from the nasal/oral secretion collected from pigs in which the vaccine was administered by the parenteral route are not recommended for eradication purposes.

The ability of the Aujeszky's disease vaccine strain to spread from vaccinated pigs to unvaccinated ones (lateral spread) must be tested by using the recommended route of administration that presents the greatest risk of spread (except for vaccines administered by the intranasal route). A repetition of the assays (four times) is necessary as this phenomenon is difficult to detect. Four piglets should be used each time for vaccination and placed in contact, 1 day later, with two unvaccinated piglets. It may also be necessary to examine the spread of the strain to nontarget species that may be susceptible to the vaccine strain.

Live attenuated vaccine strains are tested with regard to their general effects by administering to 5- to 10-day-old piglets ten times the field dose. This administration of an overdose makes it possible to detect reactions not produced under normal conditions of use. Such reactions may be produced inadvertently when large numbers of animals are vaccinated. If vaccines are administered by the intranasal route, the manufacturer has to indicate clearly that the vaccine will spread from vaccinated pigs to unvaccinated ones.

2. Inactivated vaccines

It is essential to test inactivated vaccines in the target animals under normal conditions of use for fattening pigs and for sows when this use is claimed by the manufacturer and authorised (European Pharmacopoeia, 2008; Vannier *et al*., 2007). As described previously, it is fundamental to use objective and quantifiable criteria to detect and to measure adverse reactions, such as temperature changes, weight performance, litter size, reproductive performance, etc., on vaccinated and control groups. The tests must be performed by administering the vaccine in the recommended dose and by each recommended route of administration to the pigs for which it is intended.

Pigs or sows are usually observed until there is no further evidence of vaccine reaction. The period of observation must not be fewer than 14 days from the day of administration. This period has to be extended when, for example, the vaccine is used in pregnant sows and it is necessary to assess the possible effects of the vaccine on reproductive performance. In this case, the period of observation lasts the full duration of the pregnancy.

Control authorities generally request vaccination with a double dose so that adverse reactions, which may be at the limit of detection when a single dose is administered, are more likely to be detected.

b) Local reactions

Local reactions are often associated with the use of inactivated vaccines, as these side-effects can be induced by adjuvants, particularly oil adjuvants. However, some Aujeszky's disease live vaccines are mixed with different adjuvants, which modify what has been observed in the past.

Local reactions are mainly inflammatory and can be more or less complicated (necrotic or suppurative), depending on the nature of the adjuvants used and the aseptic conditions of the vaccination. Oil adjuvants can induce a variety of effects including muscular degeneration, granuloma, fibrosis and abscessation. In addition to the nature of the oil used (the intensity of the reaction is reduced when metabolisable oils are used in the vaccine), the type of emulsion used (water/oil, oil/water, water/oil/water) induces these reactions to a greater or lesser extent. In consequence, it is necessary to observe the site of injection not only from the outside, but also by dissection after slaughter, especially for growing and finishing pigs.

ii) Field testing

Field trials are necessary to assess the safety of an Aujeszky's disease vaccine in a large number of pigs or sows. In Europe (European Pharmacopoeia, 2008), tests must be carried out in each category of animals for which the vaccine is intended (sows, fattening pigs). At least three groups of no fewer than 20 animals each are used with corresponding groups of no fewer than 10 controls. The rectal temperature of each animal is measured at the time of vaccination, 6, 24 and 48 hours later. At slaughter, the injection site must be examined for local reactions. If the vaccine is intended to be used in sows, reproductive performances have to be recorded. Field trials are supplemented by laboratory studies of efficacy correlated to vaccine potency.

2.3.2. Efficacy requirements

i) Laboratory trials

All tests must be carried out on pigs that do not have antibodies against Aujeszky's disease virus or against a subunit of the virus, except that some tests may be done using maternally immune animals.

a) Assessment of passive immunity

To test the efficacy of vaccines, it is important to mimic the natural infection conditions (European Commission, 2008). SHV-1 infection gives rise to important losses of young piglets from nonimmune sows. Thus, when vaccinating sows, the main goal is to protect the young piglets through passive immunity conferred by the colostrum ingested immediately after birth, with the secondary objective of preventing abortion.

To measure this passive immunity and the protection induced by vaccinating the sows, experimental models have been established. The sows are vaccinated according to the vaccinal protocol during pregnancy. When the piglets are, for example, 6–10 days old they are given an intranasal challenge exposure with a virulent SHV-1 strain. It is preferable to use a strain titrated in median lethal doses (LD_{50}). Pigs should be inoculated by the nasal route, 10^2 LD_{50} per pig in 1 ml. The efficacy of the vaccine is assessed by comparing clinical signs, but also and more importantly, mortality, or humane euthanasia, in piglets from unvaccinated dams with that observed in piglets from vaccinated sows.

Piglets from vaccinated sows can be found to have 80% protection against mortality compared with those from the control sows. In order for the results to be significant, it is recommended that eight vaccinated sows and four control sows be used (subject to satisfactory numbers of piglets from each sow).

b) Assessment of active immunity

1. Clinical protection

   Several criteria can be considered when measuring active immunity induced by vaccinating pigs. Generally, pigs are vaccinated at the beginning of the growing period, i.e. when they are between 9 and 12 weeks old. Laboratory trials are performed by challenging pigs at the end of the finishing period, when they weigh between 80 and 90 kg.

   In general, at least three criteria, such as rectal temperature, weight loss and clinical signs, along with mortality, are used to measure the clinical protection of pigs after vaccination and challenge (De Leeuw & Van Oirschot, 1985). The antibody titres have little predictive value for the efficacy of the vaccines. Weight loss compared between the vaccinated and control groups is the most reproducible and reliable parameter when the challenge conditions are well standardised. The measure of the difference in weight gain or loss between the two groups of pigs and, in the interval of time between challenge (day 0 and day 7), has a very good predictive value for the efficacy of the vaccines (Stellmann *et al*., 1989). Significant results can be obtained when weight performances are compared between one group of at least eight vaccinated pigs and another group of eight unvaccinated control pigs

   For challenge, it is usually preferable to use a high titre of a virulent strain, as this makes it possible to obtain a more marked difference between vaccinated and control pigs. On the basis of previous work, a challenge dose with at least 10^6 $TCID_{50}$/ml virulent strain having undergone not more than three passages on primary cells can be sufficient, but a higher titre ($10^{7.5}$ $TCID_{50}$/ml) is recommended. The oro-nasal route should be used to challenge the pigs by introducing the virulent strain in an appropriately high volume (≥4 ml).

   This method of evaluating the efficacy of SHV-1 vaccines is now well tested and has made it possible to establish an objective index for determining the efficacy of a vaccine. This index, which compares the relative weight losses between vaccinated and control pigs, can also be used for potency testing batches before release and for batch efficacy testing. However, the value of the cut-off index will be different as the conditions of the assay will not be identical. The influence of passively acquired, maternally derived antibodies on the efficacy of a vaccine must be evaluated adequately.

2. Virulent virus excretion

Additionally, it is desirable that vaccines should prevent or at least limit viral excretion from infected pigs (Vannier *et al*., 1991). When a control programme against Aujeszky's disease is based on large-scale vaccination, it is essential to choose the vaccines or the vaccinal scheme that best limits the replication of virulent virus in infected pigs. Several assays have been performed to compare vaccines on that basis.

Generally, the pigs are vaccinated and challenged at different periods. It is better, but more time-consuming, to infect pigs at the end of the finishing period. To measure the virus excretion, nasal swabs (taken at 10 cm depth in the nostrils) are taken daily from each pig from the day before challenge to at least 12 days after challenge. The swabs can be weighed before the sampling and immediately after to calculate the exact weight of collected mucus. Medium is then added to each tube containing a swab. The virus is titrated from the frozen and thawed medium.

Different indexes can be used to express the quantity of virulent virus excreted by pigs, taking into consideration the duration and the level of viral excretion, and the number of pigs excreting virulent virus.

3. Duration of immunity

It is recommended that any claims regarding the onset and duration of immunity should be supported by data from trials. Assessment of duration of immunity can be based on challenge trials or, as far as it is possible, on immunological and serological tests.

ii) Field trials

In general terms, it is extremely difficult to assess vaccine efficacy in animal populations. In order to do this, it would be necessary to vaccinate the animals in the absence of the pathogen that the vaccine protects against, then to await the moment of infection and to compare the effects of infection in vaccinated animals (or the offspring of vaccinated dams) with the effects in the unvaccinated animals of the same age, in the same building and in the same batch as the vaccinated animals (or those protected passively). As all these conditions are difficult to achieve in the field, field trials are certainly more appropriate to safety testing than to efficacy testing, except for the development of DIVA-vaccines that offer the opportunity to evaluate the effectiveness of vaccines under field conditions (Bouma, 2005).

2.3.3. Stability

Tests have to be carried out to verify the shelf life proposed by the manufacturer. These tests must always be real-time studies; they must be carried out on a sufficient number of batches (at least three) produced according to the described production process and on products stored in the final container, and normally include biological and physicochemical stability tests. The manufacturer has to provide the results of analyses that support the proposed shelf life under all proposed storage conditions. Usually, the proposed shelf life corresponds to the period for which the product is considered to be stable minus 3 months.

3. Vaccines based on biotechnology

3.1. Vaccines available and their advantages

Biotechnology combined with a better knowledge of the functions and characteristics of the SHV-1 glycoproteins helped to develop new vaccines. For example, Quint *et al.* (1987) deleted glycoprotein E-coding sequence from the NIA3 strain. This resulted in an efficient DIVA-vaccine against Aujeszky's disease, allowing differentiation of vaccinated from infected animals (DIVA vaccines). Most of the vaccines used at the moment are obtained from recombinant DNA-derived gene-deleted virus. The deletion of the genes coding for the glycoprotein E is the most commonly used, allowing an attenuated live virus vaccine to be obtained but still protecting against the clinical signs and reducing significantly

the level of the viral excretion by the pigs vaccinated and infected. Because of the ability of some glycoproteins of SHV-1 to induce strong immune responses, efficiencies of DNA vaccines, consisting of plasmids encoding these glycoproteins, were tested. Indeed, DNA vaccination has a number of advantages: ease of construction and standardised production of plasmids, no handling of infectious particles, induction of humoral and cellular immune responses, bypass of the maternal derived immunity. The pioneering study on DNA vaccination against Aujeszky's disease infection was published in 1997 (Gerdts *et al.,* 1997). The use of a novel generation of plasmid amplifying the level of gene transcription of the proteins of interest (Dory *et al.,* 2005) have been shown to be efficient strategies. These vaccines are not yet commercialised.

3.2. Special requirements for biotechnological vaccines, if any

Criteria to assess quality, safety and efficacy of the vaccines derived from the biotechnology are the same as the ones defined for conventional vaccines (see section C.2). Nevertheless special attention has to be paid to the stability of the recombinant DNA construction.

CHAPTER 3.1.3.

BLUETONGUE (INFECTION WITH BLUETONGUE VIRUS)

SUMMARY

Bluetongue (BT) is an infectious, primarily vector-borne viral disease that affects wild and domestic ruminants such as sheep, goats, cattle, buffaloes, deer and most species of African antelope, and camelids as vertebrate hosts. The virus is primarily transmitted between susceptible vertebrate hosts by competent species of Culicoides *midges, and the global distribution of the disease is largely determined by the distribution of competent vectors. Infection with bluetongue virus (BTV) is inapparent in the vast majority of animals but can cause fatal disease in a proportion of infected sheep, deer and wild ruminants. Infection of cattle is usually subclinical, with the exception of BTV-8 infection. Cattle are particularly significant in the epidemiology of the disease due to the prolonged viraemia that occurs following infection. When apparent, clinical signs of BT are mainly attributable to an increase in vascular permeability and include fever, hyperaemia and congestion, facial oedema and haemorrhages, erosion of the mucous membranes, coronitis and laminitis, and pleural and pericardial haemorrhages.*

Detection of the agent: *BTV is the type member of the* Orbivirus *genus of the family* Reoviridae*. There are 27 recognised BTV serotypes and several recently isolated but as yet unclassified unique 'atypical' strains. Virus serotype identification traditionally requires isolation and amplification of the virus in embryonated chicken eggs,* Culicoides *cells or other tissue culture and the subsequent application of serogroup- and serotype-specific tests including virus neutralisation assays. The reverse-transcription polymerase chain reaction (RT-PCR)* assay *has permitted rapid amplification of BTV cDNA in clinical samples and well validated real-time RT-PCR-based systems for virus detection are now routine, allowing for more rapid and sensitive diagnostic testing. The combination of RT-PCR amplification and capillary sequencing or whole genome sequencing now offer relatively rapid unequivocal agent identification at the genome level. Collectively, these procedures augment the classical virological techniques to provide information on virus serogroup, serotype and topotype.*

Serological tests: *Serological responses appear 7–14 days after BTV infection. Infected animals produce both neutralising and non-neutralising anti-BTV antibodies that are generally long-lasting. Enzyme-linked immunosorbent assay (ELISA) and virus neutralisation (VN) are the most frequently used serological tests. A monoclonal antibody-based competitive ELISA to specifically detect anti-BTV (serogroup-specific) antibodies is the test recommended to certify animals as free from infection prior to movement; the test is highly sensitive and specific (compared with the agar gel immunodiffusion), quick, inexpensive and reliable. However, the ELISA may have reduced sensitivity for some serotypes. Procedures to identify and quantify BTV serotype-specific antibodies are more complex, being typically based on cell culture- and live virus-dependent neutralisation tests.*

Requirements for vaccines: *Vaccination is the preferred method of BT control in endemic regions. Vaccination has been used successfully to limit direct losses, minimise the circulation of BTV, eradicate BTV from country/regions and allow safe movement of animals. However, use of live vaccines can be associated with adverse outcomes and live attenuated vaccine strains can be spread by vectors, with eventual reversion to virulence or reassortment of vaccine virus genes with those of wild-type virus strains. Inactivated vaccines are safer, but require multiple doses to become efficacious and incur higher costs. Such vaccines have been very effective in combatting the spread of BTV-8, BTV-1 and BTV-4 in Europe.*

A. INTRODUCTION

1. Description of the disease

Bluetongue (BT) is an infectious, primarily vector-borne viral disease that affects wild and domestic ruminants. Midges of an increasing number and geographical range of species (Carpenter *et al*., 2015) in the genus *Culicoides* (the insect host) typically transmit bluetongue virus (BTV) among susceptible ruminants, having become infected by feeding on viraemic animals (the vertebrate host). Other routes of transmission have been documented including direct vertical, oral and possibly venereal transmission and indirect transmission through reused needles; however the epidemiological significance of these routes remains uncertain (Belbis *et al*., 2017; Darpel *et al*., 2016; Kirkland *et al*., 2004). The more recently recognised serotypes, such as BTV-25, BTV-26 and BTV-27 appear to be transmitted exclusively by these vector-independent routes, and may result in persistent infection in goats (Belbis *et al*., 2017; MacLachlan *et al*., 2015; Vogtlin *et al.,* 2013).

The global distribution of BTV is determined by epidemiological systems (episystems) that are in turn primarily delimited by specific vector species, the presence of susceptible host species and their collective natural history. Observations in Europe, India and the USA indicate that strains of BTV can move between episystems through movement of animals, wind dispersion of infected vectors and by adaptations of both vector species and virus (Carpenter *et al*., 2015; Jacquot *et al*., 2019; Maan *et al*., 2015). The expanding global range of BTV infection has been notable, particularly at the traditional northern- and southern-most limits of BTV distribution with incursions of multiple serotypes into Europe, Australia, both North and South America, and Asia, in countries that had not previously reported BTV infections (MacLachlan *et al*., 2015; MacLachlan & Mayo, 2013). In addition to detecting and confirming an increasing number of serotypes, developing sequencing technologies, phenotyping software and molecular assays have revealed that two major ancestral lineages, a Western (Africa, Europe, the Americas) and an Eastern (Australia, and Asia) exist globally (Maan *et al*., 2015; Mertens *et al*., 2007).

In temperate parts of the world, infection has a seasonal occurrence (Verwoerd & Erasmus, 2004), whereas in tropical regions BTV infection can occur year-round (MacLachlan *et al*., 2015). Survival of BTV in the environment is associated with insect factors such as over-wintering (Mayo *et al*., 2016). Additionally, long-term persistence of BTV in a region only occurs when multiple virus serotypes circulate (MacLachlan *et al*., 2015). The ability of the more recently detected BTV serotypes 25, 26 and 27 to be transmitted in the absence of vector insects reduces the likelihood of seasonality in their occurrence or dependence on the geographical distribution of vector species for transmission.

The vertebrate hosts for BTV include both domestic and wild ruminants, such as sheep, goats, cattle, buffaloes, deer, most species of African antelope and other *Artiodactyla* such as camels. Although detection of antibodies to BTV antigen or viral nucleic acid or live virus has been demonstrated in some carnivores, black and white rhinoceroses and elephants, the role of non-ruminant species in BTV epidemiology is considered minimal. The outcome of infection ranges from subclinical in the vast majority of infected animals, especially wild African ruminants, cattle and goats, to serious or fatal in a proportion of infected sheep, goats, deer and some wild ruminants (Verwoerd & Erasmus, 2004). Infection in cattle and goats is typically subclinical and these species are considered to be amplifying reservoir hosts in endemic regions, making control measures for BTV in those animals important. However, a higher incidence and severity of clinical disease has been observed in naïve cattle infected with BTV-8. As breeds of sheep have varying levels of susceptibility to disease, BTV infections of livestock can occur unobserved and be detected only by active surveillance (Daniels *et al*., 2004).

Clinical signs of disease in sheep vary markedly in severity, influenced by the type or strain of the infecting virus, husbandry factors and animal breed (Verwoerd & Erasmus, 2004). In severe cases there is an acute febrile response characterised by hyperaemia and congestion, leading to oedema of the face, eyelids and ears, and haemorrhages and erosions of the mucous membranes. The tongue may show intense hyperaemia and become oedematous, protrude from the mouth and in severe cases become cyanotic. Hyperaemia may extend to other parts of the body particularly the coronary band of the hoof, the groin, axilla and perineum (MacLachlan & Mayo, 2013). Sheep that develop chronic disease often have severe muscle degeneration, and breaks in the wool may occur associated with pathology in the follicles. A reluctance to move is common and torticollis may occur in severe cases (Maclachlan *et al.,* 2009). In fatal cases, the lungs may show interalveolar hyperaemia, severe alveolar oedema and the bronchial tree may be filled with froth. The thoracic cavity and pericardial sac may contain varying quantities of plasma-like fluid. Most cases show a distinctive haemorrhage near the base of the pulmonary artery (Verwoerd & Erasmus, 2004). In cases of vertical transmission of BTV-8, the central nervous system may be severely affected resulting in a failure of the cerebral hemispheres to develop (dummy calf syndrome). With virulent strains, infection in naïve sheep can result in mortality rates as high as 70%.

Control of BTV in animals is covered in Chapter 8.3 of the WOAH *Terrestrial Animal Health Code*. Because of the high percentage of subclinical infections, persistent viraemia, and challenges with vector control, traditional methods of control and eradication of BTV, such as movement controls, stamping out and vector control have not always been successful in controlling the disease. Thus, a safe and efficacious vaccine that meets the objectives of control, eradication and prevention requirements is an important component of disease control in many settings (MacLachlan & Mayo, 2013).

2. Nature and classification of the pathogen

Taxonomically, BTV is classified as the type species in the *Orbivirus* genus in the family *Reoviridae*, one of 22 recognised species in the genus that also includes epizootic haemorrhagic disease virus (EHDV), equine encephalosis virus and African horse sickness virus. There is significant immunological cross-reactivity among members of the BTV serogroup. Within species, individual BTV are differentiated on the basis of genotype and neutralisation tests; currently 27 serotypes of BTV are recognised including Toggenburg Orbivirus (BTV-25), BTV-26 from Kuwait and BTV-27 from Corsica. These most recently detected serotypes and several other as yet serotypically unclassified unique BTV strains (Belbis *et al*., 2017) may exhibit quite distinct modes of transmission associated with their respective abilities to infect *Culicoides* spp. and specific ruminant hosts (Breard *et al*., 2018, Chaignat *et al*., 2009, Maan *et al*., 2015; Savini, 2015). Both genetic shift and genetic drift account for the diversity and heterogenicity of the BTV strains in the field (Pritchard *et al*., 2004).

BTV particles are composed of three protein layers. The outer capsid layer contains two proteins, VP2 and VP5. VP2 is the major neutralising antigen and determinant of serotype specificity. Removal of the outer VP2/VP5 layer leaves a bi-layered icosahedral core particle that comprises an outer layer composed entirely of capsomeres of VP7 and a complete inner capsid shell (the subcore layer) comprising VP3, which surrounds 10 dsRNA genome segments and minor structural proteins (VP1, VP4 and VP6). VP7 is a major determinant of serogroup specificity and the site of epitopes used in competitive enzyme-linked immunosorbent assays (C-ELISAs) to detect anti-BTV antibodies (Mertens *et al*., 2005). VP7 can also mediate attachment of BTV to insect cells.

Genetic sequencing of specific BTV genome segments and movement towards full genome analyses allows for additional differentiation and analysis of strains apart from serotyping, with potential to identify multiple different clades for each genome segment[1] (Gould, 1987; Jacquot *et al*., 2019). Even for strains within one serotype it is therefore possible to identify the likely geographical origin (topotype) for each genome segment (Gould, 1987). Identification of apparent associations between some genotypes of virus and some vector species has led to further development of the concept of viral-vector episystems (Daniels *et al*., 2004). Movements of several BTV serotypes between vector species and into new geographical regions, leading to multiple reassortment events and the emergence of novel strains containing new combinations of genome segments from different origins (Jacquot *et al.,* 2019; Nomikou *et al.,* 2015), indicate that a more complete identification of the genetic makeup of each strain would contribute to a better understanding of BTV epidemiology.

3. Zoonotic potential and biosafety and biosecurity requirements

There is no known risk of human infection with BTV. Biocontainment measures should be determined by risk analysis as described in Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*.

4. Differential diagnosis

Depending on the clinical presentation, affected species and epidemiological data, differential diagnoses for suspected cases of BTV infection may include other infectious diseases including but not limited to epizootic haemorrhagic disease, foot and mouth disease, peste des petits ruminants, sheep and goat pox, vesicular stomatitis and contagious ecthyma. In cases of dummy calf syndrome, bovine viral diarrhoea virus should be taken into consideration. Non-infectious causes, including photosensitisation, should also be considered.

1 See BTV-Glue database http://btv-glue.cvr.gla.ac.uk

B. DIAGNOSTIC TECHNIQUES

Table 1. Test methods available for the diagnosis of bluetongue and their purpose

Method	Purpose					
	Population freedom from infection	Individual animal freedom from infection prior to movement	Contribute to eradication policies	Confirmation of clinical cases	Prevalence of infection – surveillance	Immune status in individual animals or populations post-vaccination
Detection of the agent[a]						
Real-time RT-PCR	–	+++	–	+++	++	–
RT-PCR	–	+++	–	+++	++	–
Classical virus isolation	–	+++	–	+++	–	–
Detection of immune response						
C-ELISA (serogroup specific)	+++	+++	++	–	+++	++
VN (serotype specific)	+	+	++	+	++	++
AGID	+	+	+	–	+	+

Key: +++ = recommended for this purpose; ++ recommended but has limitations;
+ = suitable in very limited circumstances; – = not appropriate for this purpose.
RT-PCR = reverse-transcription polymerase chain reaction; C-ELISA = competitive enzyme-linked immunosorbent assay;
VN = virus neutralisation; AGID = agar gel immunodiffusion
[a]A combination of agent identification methods applied on the same clinical sample is recommended.

1. Detection of the BTV agent

1.1. *In-vitro* and *in-vivo* cultures

Specimens for virus isolation can include unclotted blood (heparin or EDTA [ethylene diamine tetra-acetic acid]-treated whole blood) from suspected viraemic animals, blood clots after separation of serum, spleen or lymph nodes collected at necropsy of clinical cases, or midges. Several virus isolation systems for BTV are in common use, including inoculation of embryonated chicken eggs (ECE) and primary inoculation of cell cultures such as the KC cell line (a cell line derived from *C. sonorensis* midges). The KC cell line has been proven to be very sensitive (McHolland & Mecham, 2003) and from an animal ethics perspective reduces the use of embryonated eggs. Attempts to isolate virus *in vitro* in mammalian cell culture systems may be considered more convenient, however the success rate is frequently much lower than that achieved with embryonated chicken egg and KC cell systems. The same diagnostic procedures are used for domestic and wild ruminants. Inoculation of sheep continues to be used for *in-vivo* testing and amplification of virus but should be avoided wherever possible in accordance with chapter 7.8 of the *Terrestrial Animal Health Code*.

1.1.1. Isolation in embryonated chicken eggs

i) Blood is collected from suspected viraemic animals into an anticoagulant such as EDTA, heparin or sodium citrate, and the blood cells are washed three times with sterile phosphate-buffered saline (PBS). Washed cells are re-suspended in PBS or isotonic sodium chloride

and either stored at 4°C or used immediately for attempted virus isolation. Tissue and midge suspension can be also prepared and stored as described above or immediately used.

ii) For long-term storage at 4°C or where refrigeration is not possible for short periods of time, blood samples are collected in oxalate–phenol–glycerine. Washed red blood cells and tissue homogenates can be stored directly at –70°C. The virus is not stable at –20°C. BTV has remained viable for several months or even years in whole blood in anticoagulant stored at 4°C.

iii) In fatal cases, spleen and lymph nodes are the preferred organs for virus isolation attempts. Organs and tissues should be kept and transported at 4°C to a laboratory where they are homogenised in PBS or isotonic saline (1/10), centrifuged at 1500 rpm for 10 minutes, and filtered (0.2–0.4 μm). The tissue suspensions can be used as described below for blood cells.

iv) Washed blood cells are re-suspended 1/1 in distilled water (to disrupt whole red blood cells) then diluted to 1/10 in PBS to ensure isotonic balance. 0.1 ml amounts are inoculated intravascularly into 5–12 ECE that are 9–12 days old. This procedure requires skill and practice. Details are provided by Clavijo *et al*. (2000).

v) The eggs are incubated in a humid chamber at 32–33.5°C and candled daily. Any embryo deaths within the first 24 hours post-inoculation are regarded as nonspecific.

vi) Embryos that die between days 2 and 7 and embryos remaining alive at 7 days are retained at 4°C overnight before harvesting. Infected embryos may have a haemorrhagic appearance. Dead embryos and those that live to 7 days are homogenised as two separate pools. Whole embryos, after removal of their heads, or pooled organs such as the liver, heart, spleen, lungs and kidney, are homogenised and the debris removed by centrifugation at 1500 ***g*** for 10 minutes.

vii) Virus in the supernatant may be identified either directly as described in Section B.1.2 below or after further amplification in cell culture, as described in Section B.1.1.2.

1.1.2. Isolation in cell culture

Virus isolation is best achieved by primary isolation (or amplification) of virus in ECE, followed by a passage in the *Aedes albopictus* (AA) clone C6/36 insect cell culture or primary isolation in cells derived from *Culicoides sonorensis* (free of BT viruses) and designated as KC or CuVa cells (McHolland & Mecham, 2003). These two amplification steps are then followed by a passage in mammalian cell lines such as baby hamster kidney (BHK 21) or African green monkey kidney (Vero). Passages in BHK 21 and Vero will enable further replication of virus and visual confirmation of virus isolation by cytopathic effect (CPE).

There have been occasions where CPE is not seen in a mammalian cell line, but BTV antigen has been visualised when staining by direct immunofluorescence. Cell monolayers are incubated at 37°C in 5% CO_2 with humidity and monitored for the appearance of CPE after 5–7 days. If no CPE appears, a second passage is made in the mammalian cell culture.

Positive CPE or immunofluorescence detection or negative cell culture results for BTV must be confirmed after each ECE, KC or cell culture passage by antigen detection ELISA or polymerase chain reaction (PCR) techniques.

1.2. Virus detection and characterisation

The success of virus isolation techniques is assessed by testing for the presence of BTV in the cell culture supernatants or embryo tissues using a variety of detection systems. Virus detection systems include antigen-capture ELISA, direct immunofluorescence, reverse-transcription PCR (RT-PCR) or real-time RT-PCR, as described in Section B.1.3 below. Currently, testing of the isolation media by real-time RT-PCR is the preferred screening method.

Detection and characterisation are typically step-wise processes, with serogroup-specific tests used initially to detect the presence of a BTV. Subsequent genotype and serotype identification of BTV isolates provides valuable epidemiological information and is critical for the implementation of vaccines or for vaccine development. RT-PCR assays employing serotype-specific primers will provide the most rapid

and specific information regarding isolate serotype (Mertens *et al.,* 2007). Genotyping for molecular epidemiology can be based on RT-PCR tests and sequencing of the amplicon. Different laboratories have standardised several different gene sequences for this purpose. Where available, full genome sequencing may also be performed to provide serotype, as well as other unique sequence information of isolates.

Neutralisation procedures using individual serotype antisera may also be employed for serotyping, although some serotypes are cross-reactive and interpretation can be difficult. For laboratories without serotyping capabilities, BTV isolates may be submitted to any WOAH BT Reference Laboratory for serotyping of isolates.

1.2.2. Immunological serogrouping of viruses

Orbivirus isolates are typically serogrouped on the basis of their reactivity with specific standard antisera that detect proteins, such as VP7, that are conserved within each serogroup. The cross-reactivity between members of the BT and EHD serogroups raises the possibility that an isolate of EHDV could be mistaken for BTV on the basis of a weak immunofluorescence reaction with a polyclonal anti-BTV antiserum. Polyclonal and monoclonal antibodies (MAbs) used for serogrouping BTV isolates must be characterised as appropriate for the purpose. There exists significant VP7 variation within BTV, as well as antigenic relatedness between other closely related orbiviruses, such as EHDV, that will influence antibodies binding in different assay formats (IFA, ELISA, AGID). For this reason, a BT serogroup-specific MAb can be used. A number of laboratories have generated such serogroup-specific reagents. Commonly used methods for the identification of viruses to serogroup level are as follows.

i) *Immunofluorescence/immunoperoxidase staining*

Monolayers of BHK or Vero cells in various tissue culture substrates (including chamber slides, glass cover-slips, 96 or 24 well plates or other suitable formats) are infected with either tissue culture-adapted virus or virus in ECE lysates. After 24–48 hours at 37°C, or after the appearance of a mild CPE, infected cells are fixed with agents such as paraformaldehyde, acetone or methanol, dried and viral antigen detected using anti-BTV antiserum or BTV-specific MAbs and standard immunofluorescent procedures. Standard immunoperoxidase staining procedures can also be used when fluorescent microscopes are not available for reading immunofluorescence, as stained antigen can be read by eye or using light microscope at 100× magnification.

ii) *Antigen capture enzyme-linked immunosorbent assay*

Viral antigen in ECE, culture medium harvests and infected insects may be detected directly using an antigen-capture ELISA (Ag ELISA). In this technique, virus derived proteins are captured by antibody adsorbed to an ELISA plate and bound materials detected using a second antibody. The capture antibody may be polyclonal or a serogroup-specific MAb. Serogroup-specific MAbs and polyclonal antibody raised to VP7 proteins or whole virus have been used successfully to detect captured virus. Antigen detection from whole blood is not always successful using the Ag ELISA.

1.2.2. Serotyping of isolates by virus neutralisation

Neutralisation tests are type specific for the currently recognised BTV serotypes that have been isolated in culture. Reference antibodies can be used to serotype a virus. In the case of an untyped isolate, the characteristic regional localisation of BTV serotypes can generally obviate the need to attempt neutralisation by antisera to all isolated serotypes, particularly when endemic serotypes are well known.

There is a variety of tissue culture-based methods available to aid in typing isolates. Cell lines commonly used are BHK, Vero and L929. Three methods to serotype BTV isolates are outlined briefly below. For antibody typing virus neutralisation methods, see Section B.2. below. There is also a fluorescence inhibition test, not described. BTV serotype-specific antisera generated in guinea-pigs or rabbits have been reported to have less serotype cross-reactivity than those made in cattle or sheep. It is important that antiserum controls be included.

i) *Plaque reduction*

The virus to be serotyped is diluted to contain approximately 100 plaque-forming units (PFU) and incubated with either no antiserum (virus control) or with serial dilutions of individual standard antisera to a panel of BTV serotypes. Virus/antiserum mixtures are added to monolayers of cells. After adsorption and removal of inoculum, monolayers are overlaid with agarose or carboxy-methyl cellulose (medium viscosity) for easy removal of semi-solid agar before staining. The neutralising antibody titres are determined as the reciprocal of the serum dilution that causes a fixed reduction (e.g. 80%) in the number of PFU. The unidentified virus is considered serologically identical to a standard serotype if the latter is run in parallel with the untyped virus in the test and is similarly neutralised.

ii) *Plaque inhibition*

Tests are performed in 90 mm diameter Petri dishes containing confluent cell monolayers that are infected with approximately 5×10^4 PFU standard or untyped virus. After adsorption and removal of inoculum, monolayers are overlaid with agarose. Standard anti-BTV antisera are added to individual filter paper discs and placed on the agarose surface. Dishes are incubated for at least 4 days. A zone of virus neutralisation, with concomitant survival of the cell monolayer, will surround the disc containing the homologous antiserum.

iii) *Microtitre neutralisation*

Approximately 100 $TCID_{50}$ (50% tissue culture infective dose) of the standard or untyped virus is added in 50 µl volumes to test wells of a flat-bottomed microtitre plate and mixed with an equal volume of standard antiserum serially diluted in tissue culture medium. Approximately 10^4 cells are added per well in a volume of 100 µl, and plates incubated for up to 7 days, depending on the level of CPE observed in negative serum wells of the test. When CPE has developed to 4+ (100%) in the negative control serum wells of each serotype tested, the test is read using an inverted microscope. Wells are scored for the degree of CPE observed. Those wells that contain cells only or cells and antiserum, should show no CPE. In contrast, wells containing cells and virus should show 75–100% CPE. The unidentified virus is considered serologically identical to a standard BTV serotype if both are neutralised in the test to a similar extent.

1.3. Molecular methods

1.3.1. Detection of nucleic acid

RT-PCR techniques provide rapid identification of BT viral nucleic acid in blood and other tissues of infected animals. Importantly, RT-PCR-based diagnostics should be interpreted with caution because the RT-PCR procedure will detect virus-specific nucleic acid after the virus is no longer viable and capable of establishing a new infection in either insects or mammalian hosts. Hence a positive RT-PCR result, does not necessarily indicate the presence of infectious virus. In addition, RNA originating from vaccine strains can be detected.

Multiple RT-PCR formats are available that can be used to detect BTV specifically to 'serogroup' Orbiviruses and to 'serotype' BTV. These molecular approaches are much more rapid than traditional virological and immunological approaches, which may require up to 4 weeks to generate information on serogroup and serotype. Developments in molecular assays, new sequencing technologies and phenotyping software have identified increasing numbers of new serotypes, methods of transmission, and host-specific susceptibility patterns.

The nucleic acid sequence of cognate BTV genes may differ depending on the geographical area of virus isolation (Gould, 1987; Maan *et al.,* 2015). This has provided a unique opportunity to complement studies of BTV epidemiology by providing information on the potential geographical origin of virus isolates, a process termed genotyping or topotyping. While sequencing of BTV isolates from different parts of the world may allow detection of various clades for each genome segment, which may permit finer discrimination of geographical origin, the relationship between sequence and geographical origin is not absolute in all cases. Thus, BTV sequencing information is vitally important and all data regarding BTV segment sequences should be made widely available by submitting appropriately validated data to reputable sequence databases such as

GenBank (https://www.ncbi.nlm.nih.gov/genbank/). The BTV-Glue website (http://btv-glue.cvr.gla.ac.uk) can provide phylogenetic tree analyses of BTV isolates based on the sequence of RNA segments. These compiled data will provide a resource for epidemiological studies, the identification of new isolates, as well as supporting *in-silico* analyses for maintenance and validation of existing RT-PCR assays and the design of new primers probes for development of additional assays, e.g. for novel/variant BTV types/strains.

The capacity of RT-PCR assays to detect very small numbers of nucleic acid molecules means that such tests are exquisitely sensitive to contamination by extraneous nucleic acids leading to false positive results. False negatives, due for example to poor nucleic acid preparation or inappropriate primers, may also be encountered. This is covered in detail in Chapter 1.1.6 *Validation of diagnostic assays for infectious diseases of terrestrial animals*.

There are many RT-PCR assays currently in use that use different extraction methods, reverse transcriptases, amplification enzymes, primers and conditions. Technology is changing rapidly, and the genetic diversity of the BTV genes makes the choice and validation of RT-PCR assays conditional on its application in a regional setting. Therefore, the procedures listed below are examples only.

Two BTV RT-PCR assays are presented here: a real-time assay (Hofmann *et al*., 2008), targeting the NS3 gene segment and a conventional nested assay targeting the NS1 gene segment, using primers designed by Katz *et al*. (1993). The nested assay has been successfully used for over 20 years and can detect serotypes 1–24 and 26 (there are no reports of testing of other serotypes from multiple species. The nested assay may be beneficial for laboratories without the capacity to perform real-time RT-PCR. The real-time RT-PCR assay presented below has been tested at several laboratories world-wide and has been found capable of detecting all 27 serotypes of BTV (as well as other recently detected novel BTV strains), and equals or surpasses the sensitivity of the nested assay while providing rapid, quantitative detection of BTV without the contamination risks associated with nested RT-PCR assays.

1.3.1.1. Real-time reverse-transcription polymerase chain reaction

Real-time RT-PCR methods provide sensitive and rapid detection of BTV in a one-step procedure. Advantages of real-time methods over traditional PCR methods include rapidity of testing, quantitation of the virus present, and the reduced opportunity for contamination to occur as no post-amplification handling such as gel electrophoresis is needed. The real-time RT-PCR assays are the tests of choice for diagnosis.

The method presented here is an adaption from Hofmann *et al.* (2008) and is capable of detecting all known BTV serotypes and strains currently circulating. The assay targets BTV segment 10 (NS3). The procedure given may require modification to accommodate individual laboratory or different RT-PCR kit requirements.

i) RNA extraction from blood, tissue samples, and midges

Commercial kits are widely available; the RNA extraction step can be performed according to the procedures specified in each kit.

ii) Real-time reverse-transcription polymerase chain reaction

Kits for the one-step real-time PCR are available commercially. Below are some basic steps as described by Hofmann *et al*. (2008), which can be modified depending upon local/case-specific requirements, kits used and equipment available.

Primer and probe sequences for the detection of BTV species viruses:

BTV_IVI_F 5'-TGG-AYA-AAG-CRA-TGT-CAA-A-3'

BTV_IVI_R 5'-ACR-TCA-TCA-CGA-AAC-GCT-TC-3'

BTV_IVI_P 5'FAM-ARG-CTG-CAT-TCG-CAT-CGT-ACG- C-3' BHQ1

a) Primer stock solutions are diluted to a working concentration of 20 pmol/µl, whereas probe is diluted to a working concentration of 5 pmol/µl.

b) A test plate layout should be designed and loaded into the real-time PCR machine software. Using the layout as a guide, 0.5 µl of each primer working stock (20 pmol/µl) is added to each well that will go on to contain RNA samples, positive or negative controls. The plate is held on ice.

Note: PCR plates can be replaced with tubes or strips as appropriate.

c) 2 µl of RNA samples, including test and positive and negative controls, are added to appropriate wells of the plate following the layout (note: these wells already contain primers from step b).

d) Heat denaturation: 95°C for 5 minutes, hold on ice for further 3 minutes.

e) An appropriate volume of real-time one-step RT-PCR master mix for the number of samples to be tested is prepared, following the manufacturer's instructions. Probe should be included in the master mix to give a final concentration of 0.2 pmol/µl per sample.

f) 22 µl of master mix is distributed in each well on the PCR plate containing the denatured primers and RNA.

g) The plate is placed in a real-time thermal cycler programmed for reverse transcription and cDNA amplification/fluorescence detection as suggested by the manufacturers. The following thermal profile is an example:

	48°C	30 minutes
	95°C	2 minutes
50 cycles:	95°C	15 seconds
	56°C	30 seconds
	72°C	×30 seconds

1.3.1.2. Reverse-transcription polymerase chain reaction – nested PCR

Select RT-PCR (reverse-transcription and first stage amplification) and PCR (nested amplification) kits are available to perform the nested assay. The assay presented below for illustration uses the parameters associated with a specific kit. The PCR parameters should be adjusted according to the manufacturer's recommendations for the specific kits to be used.

The nested assay employs the use of the following primers:

First stage amplification (outer) (dilute to 25 pmol/µl; final concentration in PCR is 0.6 µM each):

FW: GTT-CTC-TAG-TTG-GCA-ACC-ACC
RV: AGG-CCA-GAC-TGT-TTC-CCG-AT

Nested amplification (dilute to 25 pmol/µl; final concentration in PCR is 0.5 µM each):

nFW: GCA-GCA-TTT-TGA-GAG-AGC-GA
nRV: CCC-GAT-CAT-ACA-TTG-CTT-CCT

i) Prepare the first stage amplification mixture (one-step RT-PCR kit) of the following reagents (per sample):

Nuclease-free water	11.8 µl
5× one-step RT-PCR buffer	5.0 µl
dNTP mix	1.0 µl
Enzyme	1.0 µl
FW primer (25 pmol/µl	0.6 µl
RV primer (25 pmol/µl)	0.6 µl

ii) Dispense 20 µl of the mixture into each PCR tube included in the assay. Add 5 µl of sample or control denatured RNA (described above) to the appropriate tube. Place tubes in a thermal cycler and run the following programme:

Reverse transcription	50°C	30 minutes
Taq activation	95°C	15 minutes
Followed by 35 cycles of:		
Denature:	94°C	45 seconds
Anneal:	58°C	45 seconds
Extension	72°C	60 seconds (final extension 10 minutes)

iii) Prepare a nested PCR mixture (HotStarTaq DNA Polymerase kit) of the following reagents (per sample):

Nuclease-free water	40.75 µl
10×HotStar buffer	5.0 µl
dNTP mix	1.0 µl
HotStarTaq	0.25 µl
nFW primer (25 pmol/µl)	1.0 µl
nRV primer (25 pmol/µl)	1.0 µl

iv) Dispense 49 µl of the mixture into each PCR tube. Transfer 1.0 µl of the amplified DNA from the first stage reaction (step 2) to the appropriate nested tube. Change gloves between samples and use caution when transferring the DNA to avoid cross contamination of samples. Place tubes in a thermal cycler and run the following programme:

Taq activation	95°C	15 minutes
Followed by 28 cycles of:		
Denature:	94°C	45 seconds
Anneal:	62°C	45 seconds
Extension:	72°C	1 minute (final extension 10 minutes)

Perform gel electrophoresis followed by modern gel visualisation methods on the nested PCR product. The positive control(s) and any positive samples will have a 101 base pair band. Negative controls and negative samples should not have a visible band. Positive samples may be sequenced for verification.

1.3.2. Nucleic acid sequencing

Although PCR-based methods can provide a rapid prospective determination of the serotype and genotype of a BTV isolate, the nucleic sequence of specific BTV genome segments is required for ultimate unequivocal identification. Through the exploitation of information provided by real-time RT-PCR or serology, and the now extensive availability of BTV sequence databases that better inform primer design, the combination of RT-PCR amplification and high throughput capillary sequencing can offer a relatively rapid, confirmative diagnostic approach. The now more economically viable option of whole genome sequencing (WGS) is also being increasingly routinely applied to BTV diagnosis (Belbis *et al*., 2017). However, the concentration of BTV in field isolations can provide limitations to the effectiveness of these sequencing approaches and prior establishment of growth in cell culture may be required for some isolates. Care should be taken concerning interpretation of results obtained with tissue culture grown virus samples, as the process of adaptation to cell culture inevitably involves selection of those viruses that can infect and replicate in the culture system used. The sequences generated may not therefore fully represent the virus population present in the original diagnostic sample.

2. Serological tests

Serological responses appear 7–14 days after BTV infection. Infected animals produce both neutralising and non-neutralising anti-BTV antibodies that are generally long-lasting. Anti-BTV antibodies generated in infected animals can be detected in a variety of ways that vary in sensitivity and specificity. Both serogroup-specific and serotype-specific antibodies are elicited and if the animal was not previously exposed to BTV, the neutralising antibodies generated are specific for the serotype of the infecting virus. Multiple infections with different BTV serotypes lead to the production of antibodies capable of neutralising serotypes to which the animal has not been exposed.

2.1. Competitive enzyme-linked immunosorbent assay

The BT competitive or blocking ELISA (C-ELISA) was developed to measure BTV-specific antibody without detecting cross-reacting antibody to other Orbiviruses (Afshar *et al*., 1989; Lunt *et al*., 1988). The specificity is the result of using BT serogroup-reactive MAbs. These antibodies were derived in separate laboratories, and although possessing different properties or epitope specificities, all appear to bind to the amino-terminal region of the major core protein VP7. In the C-ELISA, antibodies in test sera compete with the MAbs for binding to antigen. The following procedure for the C-ELISA has been standardised after comparative studies in a number of international laboratories. Importantly, monoclonal antibody-based competitive ELISA formats have been known to not detect all serotypes of BTV (particularly some BTV-15). Use of such ELISAs therefore requires an understanding of the test's fitness for purpose, and the assay must be validated accordingly to avoid missing detection of some BTV serotypes, including the novel serotypes recently identified.

2.1.1. Test procedure

There are several test procedures described; this is an example of one BT ELISA procedure.

i) First, 96-well microtitre plates are coated at 4°C overnight or at 37°C for 1 hour with 50–100 µl of either tissue culture-derived sonicated cell culture antigen or the major core antigen VP7 expressed in either *Baculovirus* (Oldfield *et al*., 1990) or yeast (Martyn *et al*., 1990) and diluted in 0.05 M carbonate buffer, pH 9.6.

ii) The plates are washed five times with PBST (0.01 M PBS containing 0.05% or 0.1% Tween 20, pH 7.2).

iii) Next, 50 µl of test sera is added in duplicate at a single dilution, either 1/5 (Afshar *et al.,* 1989) or 1/10 (Lunt *et al*., 1988) in PBST containing 3% bovine serum albumin (BSA).

iv) Immediately, 50 µl of a predetermined dilution of MAb diluted in PBST containing 3% BSA is added to each well. MAb control wells contain diluent buffer in place of test serum.

v) Plates are incubated for 1 hour at 37°C or 3 hours at 25°C, with continuous shaking.

vi) After washing as described above, wells are filled with 100 µl of an appropriate dilution of horseradish peroxidase-labelled rabbit anti-mouse IgG (H+L) in PBST containing 2% normal bovine serum.

vii) Following incubation for 1 hour at 37°C, the conjugate solution is discarded and plates are washed five times using PBS or PBST. Wells are filled with 100 µl substrate solution containing 1.0 mM ABTS (2,2'-azino-bis-[3-ethylbenzothiazoline-6-sulphonic acid]), 4 mM H_2O_2 in 50 mM sodium citrate, pH 4.0, and the plates are shaken at 25°C for 30 minutes. (Other substrates may be used and the reaction continued with shaking for an appropriate length of time to permit colour development.)

viii) The reaction is stopped by addition of a stopping reagent, such as sodium azide.

ix) After blanking the ELISA reader on wells containing substrate and stopping reagent, the absorbance values are measured at 414 nm. Results are expressed as per cent inhibition and are derived from the mean absorbance values for each sample by the following formula:

% inhibition = 100 – [(mean absorbance test sample)/(mean absorbance MAb control) × 100].

NB: Some laboratories prefer to use a negative control serum that has previously been shown to have a percentage inhibition of zero as an alternative to the MAb control.

x) Percentage inhibition values >50% are deemed positive. Inhibition between 40% and 50% is considered to be suspicious. The results of the test sera duplicates can vary as long as the results do not lie either side of the positive cut -off.

xi) Strong and weak positive sera and a negative serum should be included on each plate. The weak positive should give 60–80% inhibition and the negative should give less than 40% inhibition.

A number of commercially produced C-ELISAs based on recombinant VP7 and anti-VP7 MAb are now available. These commercial assays are routinely used in many laboratories across the world and have been proved to be fit for purpose in ring-trials (Batten *et al*., 2008). Formal acceptance for trade purposes should depend on adoption of individual kits to the WOAH Register.

Genetic divergence of certain BTV strains (e.g. different regional groups or topotypes) may affect the nature of serogroup-reactive antibodies. It is therefore possible that diagnostic characteristics for antibody detection are not uniform for all viruses encompassed by the serogroup. Diagnostic reagents and kits produced in one region may not have the same performance characteristics when used in another region. This should be addressed in considerations of fitness for purpose.

2.2. Indirect ELISA

An indirect ELISA for bulk milk samples has been shown to be reliable and useful for surveillance purposes (Kramps *et al*., 2008). It should be validated for relevant serotypes before use. While an indirect ELISA may have the disadvantage of cross reactivity with related viruses such as EHDV, it does have high analytical sensitivity and could be a useful screening assay in some situations.

2.3. Virus neutralisation serology

VN serology can identify serotype-specific neutralising antibodies as well as determine their titre. It is an important additional test in endemic areas where multiple serotypes are likely to be present. Its capability to identify the serotype involved in an outbreak is essential for putting in place appropriate control measures such as vaccination or animal movement restrictions. It is also useful for epidemiological surveillance, transmission studies and for determining useful antibody response to vaccination. Cross-neutralising antibodies can develop in animals that have experienced BTV infection. Importantly, infection with a second or third serotype can broaden the neutralising antibody response to include antibodies to serotypes to which the animal has not been exposed. The application of VN serology is frequently most useful in conjunction with other virological investigations that, in combination, can provide a more definitive basis for resolving serotype distribution. The use of the plaque reduction test (modified from Section B.1.2.2) can improve resolution of serotype involvement, where this is unclear on a standard VN test due to its quantitative nature.

2.3.1. Test procedure

Several methods to determine titre and serotype of BTV have been described; here the procedure that has been standardised after comparative studies in various international laboratories is briefly outlined. Indicator cell lines commonly used are BHK and Vero. It is important that well characterised, reference positive and negative control antiserum be included in each test.

i) 50 µl of serial sera dilutions, from 1/10 to 1/1280, are added to each test well of flat-bottomed microtitre plates and each well is mixed with an equal volume of medium containing approximately 100 $TCID_{50}$ of suitable, well characterised, BTV reference viruses. Note the selection of reference strains used will be dependent on the circulating (or possibly circulating) serotypes in the testing population.

ii) The plates are incubated in a humid chamber at 37°C in 5% CO_2.

iii) After 1 hour of incubation, approximately 10^4 Vero or BHK-21 cells are added per well in a volume of 100 µl of suitable media (containing) able to sustain growth of the chosen cells.

iv) Incubate at 37°C for up to 7 days, depending on the level of CPE obtained in normal serum wells of the test. When CPE has developed to 100% in the normal serum wells of each serotype tested, the test is read using a light microscope at 100× magnification to determine presence of CPE.

v) Wells are scored for the degree of CPE observed. A sample is considered positive when it nears full neutralisation, allowing for the acceptance of trace CPE at the lowest dilution (1/10). The presence of trailing trace CPE may indicate evidence of partial neutralisation. In these situations, the reference virus used may not be representative of contemporary circulating viruses and further investigation may be required (for example, use of the plaque reduction

neutralisation test, which is superior in resolving cross reactivity between related serotypes). The serum titre represents the highest serum dilution capable of near complete neutralisation of 50% of replicate test wells. A fourfold difference in endpoint titre obtained from different serotypes tested can indicate the serotype involved in an infection. Cross reactions are known to occur between serotypes in the VN test even when only one serotype is involved.

2.4. Agar gel immunodiffusion

It must be recognised that a major disadvantage of the AGID used for BT is its lack of specificity in that it does not exclusively differentiate between antibodies to the BT and EHD serogroups. Hence, it cannot be used definitively to detect antibodies to BTV as a positive reaction may have been the result of an infection to another *Orbivirus* species. Notably, the AGID test is simple to perform and the antigen used in the assay relatively easy to produce. Since 1982, the test has been one of the standard testing procedures for international movement of ruminants, however, it is no longer considered sufficiently accurate for use in the support of international trade. The assay does have a role in the investigation of samples that give inconsistent results in other assays. AGID positive sera should be retested using a BT serogroup-specific assay if BTV specificity is required. The preferred test, a C-ELISA, is described in Section B.2.1.

C. REQUIREMENTS FOR VACCINES

1. Background

Vaccination with effective vaccines is the preferred method of BTV control in endemic countries. Vaccination has been used successfully to limit direct losses, minimise the circulation of BTV, eradicate BTV from a region, and allow safe movement of animals. Both live attenuated and inactivated BTV vaccines are currently available for use in sheep and sheep and cattle, respectively. Recombinant BT vaccines based on various approaches are under development (van Rijn, 2019), but none has been licensed and these vaccines will not be addressed here.

Live attenuated vaccines are inexpensive to produce in large quantities; they generate protective immunity after a single inoculation and have proven effective in preventing clinical BT disease in the areas where they are used. In South Africa, live attenuated vaccines have been used for over 50 years and are known to induce an effective and lasting immunity. Live attenuated vaccines are produced by adapting BTV field isolates to growth *in vitro* through serial passages in tissue culture or in ECEs. Stimulation of a strong antibody response by these vaccines is directly correlated to their ability to replicate in the vaccinated host. However, live attenuated BTV vaccines suffer from a variety of documented or potential adverse outcomes, including depressed milk production, abortion/embryonic death, teratogenesis and congenital defects, and have been documented to be spread by vectors with considerable potential for reversion to virulence and reassortment of vaccine virus genes with those of wild-type virus strains (Ferrari *et al*., 2005; Ranjin *et al*., 2019; Savini *et al.,* 2014). Under-attenuation, the impact of which may vary with different breeds of sheep (Veronesi *et al*., 2010), and reassortment with other vaccine and field strains (Nomikou *et al*., 2015) may also occur. The frequency and significance of these events remain poorly defined but transmission of vaccine strains by vector midges has already been documented in the USA, South Africa and Europe (Ferrari *et al*., 2005).

Inactivated vaccines containing tissue-culture grown and chemically inactivated vaccine strains are far safer but require multiple doses to become efficacious and incur higher costs. Such vaccines have been very effective in combatting the spread of BTV-8 in Europe. Whilst inactivated vaccines (as with live vaccines) are not compatible with serological assays for detection of infection in vaccinated animals (DIVA strategies), surveillance can be maintained after their use by RNA based (RT-PCR) assays.

Additionally, non-BTV vaccines for both target and non-target species have been found to be contaminated with BTV leading to abortion, heart failure, respiratory distress and death in non-ruminant species. These drawbacks have resulted in a great deal of research and development of BTV vaccines that are safe, efficacious against multiple serotypes, inexpensive, are DIVA capable, only require a single dose with rapid onset of immunity, and block viraemia. Recent efforts with reverse genetics and molecular technology has led to next generation vaccines that balance these often competing requirements while meeting specific field situation needs.

Guidelines for the production of veterinary vaccines are given in Chapter 1.1.8 *Principles of veterinary vaccine production*. The guidelines given below and in chapter 1.1.8 are intended to be general in nature and may be supplemented by national and regional requirements.

2. Outline of production and minimum requirements for vaccines

2.1. Characteristics of the seed

See chapter 1.1.8 for general requirements for master seeds and allowable passages for vaccine production.

2.1.1. Biological characteristics of the master seed

For live attenuated vaccines, the master or primary virus seed is prepared from a single plaque of serially passaged, attenuated BTV. Vaccine viruses have been attenuated by either passage in ECE, tissue culture cells or a combination of both. Each primary seed virus lot should also be tested for transmissibility and reversion to virulence prior to vaccine manufacture. Samples of vaccine prepared from secondary seed virus at the maximum permitted passage level should be tested in sheep for avirulence, safety and immunogenicity.

For inactivated vaccines, the issues of attenuation do not apply, and the approach adopted has been to use field strains of low passage level with the intent of achieving high antigenicity.

2.1.2. Quality criteria (sterility, purity, freedom from extraneous agents)

Primary seed virus must be free of contaminating bacteria, viruses, prions, fungi and mycoplasmas, particularly pestivirus contamination. For the latter, attention should be paid to the fetal bovine serum used in cell cultures, as it may be contaminated. Seed viruses must be shown to have the desired serotype specificity. BTV seed lot viruses should be sequenced and the data made available to relevant databases. Secondary seed lots, which are used as inocula for vaccine production, are usually not more than three passages beyond the primary seed lot.

2.1.3. Validation as a vaccine strain

Live attenuated BT vaccines must be safe and efficacious, and a brief description of appropriate tests for these parameters is given below. In addition, attenuated viruses should not revert to virulence during replication in vaccinated animals or be able to be transmitted from such animals by insect vectors. The latter criterion is very important because insect-mediated transmission of attenuated virus from vaccinated to non-immune animals, with the subsequent replicative steps in each host species, increases the possibility of reversion to virulence. Although tests for reversion to virulence and transmissibility are rarely, if ever performed, a brief description of what may be necessary is outlined.

There is a variation in BT susceptibility between breeds of sheep; it is important that sheep that have been proven to be susceptible to infection with BTV be used for vaccine validation.

2.1.4. Emergency procedure for provisional acceptance of new master seed virus (MSV) in the case of an epizootic

In a number of different circumstances (see Chapter 1.1.10 *Vaccine banks*) and in the event that a new or different serotype or variant of BTV results in an emergency epizootic situation that cannot be controlled by currently available vaccines, and where there is not enough time to fully test a new MSV for all extraneous agents, provisional acceptance of the new strain could be based on a risk analysis of the possibility of contamination of the antigen produced from the new MSV with extraneous agents. This risk assessment should take into account the characteristics of the process, including the nature and concentration of the inactivant for inactivated vaccines, before allowing or not the early release of the new product.

2.2. Method of manufacture

2.2.1. Procedure

Attenuation of field isolates of BTV was first achieved by serial passage in ECE. Because of the concern about transmission of the egg propagated attenuated virus, it has been recommended that animals receiving vaccines produced in ECE should not be moved internationally. More recently, it is accepted that passage in cultured cells will also result in attenuation of virulence. No studies have been done to precisely relate passage number and extent of attenuation for individual virus isolates or serotypes. To prepare attenuated virus, field isolates are adapted to cell culture and passaged *in vitro* up to 40 times or more. Ideally, a number of plaque-purified viruses are picked at this stage and each is examined to determine the level of viraemia they generate and their ability to elicit a protective immune response in vaccinated sheep. The most suitable virus is one that replicates to low titre but generates a protective immune response, and this may represent the source of vaccine primary seed stock virus.

BTV for inactivated vaccines is produced in large-scale suspension cell systems under aseptic and controlled conditions. Cell lines adapted for large scale industrial cultures are used and these are proven to be free from contaminating microorganisms. When the viral suspension virus reaches its maximum titre, followed by cell disruption, the culture is clarified and filtered. Subsequently inactivation is performed according to processes adopted by the manufacturer, such as by addition of binary ethyleneiminee (BEI) or other inactivating agents. The process must comply with legislation relevant for the intended market, be validated to ensure complete inactivation and supported by appropriate documentation. The inactivation process should not significantly alter the immunogenic properties of the viral antigens. Purification is carried out by chromatography. The inactivated virus is then concentrated by ultrafiltration and stored. The inactivated, chromatography-purified and concentrated BTV antigens are made into vaccine by dilution in a buffer solution and addition of adjuvants.

2.2.2. Requirements for ingredients

All ingredients of animal origin, including serum and cells must be checked for the presence of viable bacteria, viruses, fungi or mycoplasma. For further details, see chapter 1.1.8 for general guidance on ingredients of animal origin. Ingredients of animal origin should be sourced from a country with negligible risk for transmissible spongiform encephalopathies.

2.2.3. In-process controls

Virus concentration of live attenuated vaccines is assessed by infectivity and ELISAs.

For inactivated vaccines, during inactivation of the virus, timed samples are taken at regular intervals for the purpose of monitoring the rate and linearity of the inactivation process. Virus titres in the samples are determined by inoculation of BHK-21 or other appropriate cell cultures. At the end of the inactivation process, the vaccine is checked to ensure that there is no live virus.

2.2.4. Final product batch tests

i) Sterility

Every batch of vaccine should be tested for the presence of contaminant viruses, viable bacterial, fungi or mycoplasma. For example, in South Africa a pool of ten randomly selected ampoules are inoculated into soya broth and thioglycolate broth, and incubated at room temperature and 37°C for 14 days, respectively. If contaminated, the batch is disqualified.

ii) Safety

Every batch of attenuated vaccine is safety tested in newborn and adult mice or guinea-pigs. If any adverse reactions or significant signs are noted, the test is repeated. Any increase in the body temperature of the test animal that is above the level expected for the strain of attenuated virus under test should be regarded as symptomatic. If the results are unsatisfactory after a second attempt, the batch is disqualified.

Safety testing of inactivated vaccines is conducted to ensure side effects are not observed.

iii) Potency

Each batch is tested by inoculation of susceptible sheep. Pre-vaccination, 21- and 28-day post-vaccination sera are tested by VN assay to determine neutralising antibody levels. To be passed, the antibody titre must be equal to or higher than a set standard based on international vaccine standards.

iv) Duration of immunity

Studies with live attenuated BTV vaccine have shown that antibodies in sheep may appear before day 10 post-vaccination, reach a maximum approximately 4 weeks later and persist for well over a year. There is a temporal relationship between the increase in neutralising antibody titre and clearance of virus from the peripheral circulation. Live attenuated BTV vaccines have been in use for over 50 years and are known to induce an effective and lasting immunity in sheep (Verwoerd & Erasmus, 2004). Many serotypes of BTV may be present in endemic areas of South Africa, and polyvalent vaccines are used. The inclusion of 15 serotypes in three polyvalent vaccines that are administered sequentially sometimes means that an effective immune response is not generated to all serotypes, presumably because of the antigenic mass of individual serotype-specific antigens is small. In an attempt to broaden the response, vaccination is repeated annually.

Initial studies with inactivated vaccines show that antibody against BTV can be detected by day 7 post-vaccination and increase in titre to days 14–21. A second dose of vaccine boosts the titre. Data to demonstrate the expected duration of immunity are being acquired.

v) Stability

Procedures have been developed for attenuated vaccines. Stability should be tested over a period of 2 years. Vaccines in liquid and lyophilised forms are deemed to have shelf lives of 1 and 2 years, respectively. Each batch of vaccine is subjected to an accelerated shelf-life test by storing it at 37°C for 7 days. It is then titrated and evaluated according to a set standard, as determined in the initial testing of the vaccine. Shelf life of stock aliquots stored at +4°C should be tested periodically.

2.3. Requirements for regulatory approval

2.3.1. Manufacturing process

For registration of vaccine, all relevant details concerning manufacture of the vaccine and quality control testing (see Section C.2.1 and C.2.2) should be submitted to the authorities. This information shall be provided from three consecutive vaccine batches with a volume not less than 1/3 of the typical industrial batch volume.

2.3.2. Safety requirements

All vaccines must be safety tested. Safety tests for attenuated vaccines do not address the issue of their teratogenicity. Attenuated virus vaccines are teratogenic and should not be administered to pregnant sheep during the first half of pregnancy as this may cause fetal abnormalities and embryo death.

i) Target and non-target animal safety

Demonstration of avirulence is necessary for live, attenuated vaccines. A number of sheep seronegative by an appropriate, sensitive serological test (that will reliably detect antibodies even in vaccinated animals), are inoculated with the primary seed stock. Temperatures are noted twice daily. The animals are monitored at regular intervals over a period of 28 days for clinical signs and any local or systemic reactions to ensure avirulence and innocuity. Blood samples removed at regular intervals can be used to measure level of viraemia and antibody responses. The test shall be valid if all of the vaccinated sheep show evidence of virus replication and do not display signs of disease other than mild transient illness. In South Africa, a clinical reaction index is calculated for each animal between days 4 and 14 and must be below a specific standard value.

ii) Reversion-to-virulence for attenuated/live vaccines and environmental considerations

Transmissibility is an issue with live attenuated vaccines but not with killed vaccines. Procedures to determine if attenuated virus can be transmitted by insects that feed on vaccinated, viraemic sheep are difficult to perform and analyse statistically, and consequently, this criterion of vaccine validation is rarely sought. Laboratory data indicate that laboratory-adapted viruses can be transmitted by insect vectors (Ferrari *et al.,* 2005). A suitable procedure to determine attenuated virus transmissibility requires that sheep be vaccinated and, during viraemia, that they be exposed to competent, uninfected *Culicoides*, which are then permitted to feed on uninfected animals that are monitored for the presence of BTV and anti-BTV antibody. As the titre of attenuated virus in the blood of vaccinated sheep is usually low, very large numbers of *Culicoides* may be needed and only a small proportion of these would become infected and live long enough to feed on and potentially transmit the virus to other uninfected sheep. It is difficult to design a laboratory experiment that takes account of the large numbers of vaccinated sheep and insects that would be present in field situations. Although virus titres in blood less than 10^3 $TCID_{50}$/ml have traditionally been considered a "safe" threshold, authentic instances of insects acquiring BTV from animals with viraemic titres much less than 10^3 $TCID_{50}$/ml have been reported. Given the complex interaction of BTV, *Culicoides* vectors and animal hosts in the life cycle of infection, virus titres induced by live attenuated vaccine should be kept to an absolute minimum especially if field transmission of vaccine strains is a concern.

Current data indicate that during viraemia and in contrast to wild-type virus, laboratory-adapted strains of BTV may be found in the semen of bulls and rams (Kirkland *et al.,* 2004). The implications of these observations for virus transmissibility are unclear. A recent study of semen from rams vaccinated with BTV-2 live attenuated vaccine showed that even if BTV was not detected in the semen, the vaccine caused a decrease in the quality of the semen (Breard *et al.,* 2007).

Validation studies confirm that attenuated viruses do not revert to virulence in vaccinated sheep. However, if attenuated viruses can be transmitted from vaccinated animals, reversion to virulence following several sheep-insect replication cycles becomes a distinct prospect. The only appropriate way to monitor for reversion to virulence under these circumstances is to compare the virulence of the vaccine virus with that which had been subject to several sheep–insect replication cycles as described above. As indicated, this is difficult to achieve. Consequently, the effect of sheep/insect passages on the virulence of attenuated viruses has not been determined. In South Africa, it is accepted that if blood from vaccinated animals during the viraemic stages is serially passaged three times in sheep without reversion to virulence, the chances of reversion in the field will be infinitely small. In Europe, five passages are required.

iii) Precautions (hazards)

Attenuated vaccines should be used in the cooler months when adult *Culicoides* vector populations are at a minimum. They should not be used in ewes during the first half of pregnancy and in rams 2 months before the breeding season

2.3.3. Efficacy requirements

Vaccinated and unvaccinated sheep known to be susceptible to BT disease should be challenged with virulent homologous serotype. It is recommended that the challenge model preferably use virus passaged only in ruminant animals and with no or limited ECE or cell culture passages. Passage in such an isolation system results in viral cultures that might induce clinical BT disease that is milder than the natural disease. Animals are monitored for clinical signs of BT disease, rectal temperatures are taken twice daily and blood samples removed at regular intervals to measure viraemia and antibody responses. Unvaccinated control sheep should show clinical signs of BT disease and viraemia. However, it is difficult to be certain of the appearance of clinical disease following inoculation of sheep with certain BTV serotypes and isolates, and consequently, evidence of infection of unvaccinated control sheep may rest on the appearance of a temperature rise above 40°C and a viraemia. As a further evidence of infection pre- and post-vaccination sera are checked for the presence of neutralising antibody.

2.3.4. Vaccines permitting a DIVA strategy (detection of infection in vaccinated animals)

The live attenuated and inactivated products now commercially available do not allow any DIVA strategy via serological testing.

RT-PCR may be used as DIVA assays, allowing surveillance to be maintained during inactivated vaccination campaigns. DIVA strategies may be possible using PCR-based test systems in populations in which inactivated vaccines have been applied. The inactivated vaccines may generate a very weak RT-PCR signal although this disappears a few days post-vaccination. In contrast, infected animals usually maintain a high RT-PCR signal that can last for several weeks to months, even in the presence of neutralising antibodies, due to the haemagglutinin activity associated with outer capsid protein VP2. A similar approach is not possible with currently available live attenuated vaccines. The generation of weak signal due to very early infection should also be considered if using this strategy.

2.3.5. Duration of immunity

Studies to determine a minimum duration of immunity should be conducted before the vaccine receives final approval. Duration of immunity should be demonstrated in a manner similar to the original efficacy study, challenging animals at the end of the claimed period of protection. At a minimum, the duration should be for the length of the mosquito season in areas with seasonal infections. It may be desirable to demonstrate longer immunity for animals at higher risk and in infected areas with year-round mosquito activity.

2.3.6. Stability

Live and inactivated vaccines are typically assigned an initial dating of 18 or 24 months, respectively, before expiry. Real-time stability studies should be conducted to confirm the appropriateness of all expiration dating. Product labelling should specify proper storage conditions.

CHAPTER 3.1.4.

BRUCELLOSIS (INFECTION WITH *B. ABORTUS, B. MELITENSIS* AND *B. SUIS*)

SUMMARY

Description of the disease: *Brucellosis is the generic name used for the animal and human infections caused by several species of the genus Brucella, mainly Brucella abortus, B. melitensis and B. suis. Infection with Brucella in cattle is usually caused by B. abortus, less frequently by B. melitensis, and occasionally by B. suis. Brucella melitensis is the main causative agent of infection with Brucella in sheep and goats. Brucella melitensis and B. abortus may also infect other species, including camels. Infection with Brucella in pigs is due to B. suis biovars 1–3, but the disease caused by biovar 2 differs in its host range and its limited geographical distribution. In some areas, B. suis infection has become established in wild pigs. Clinically, infection with Brucella in animals is characterised by one or more of the following signs: abortion, infertility, retained placenta, orchitis, epididymitis and, rarely, arthritis, with excretion of the organisms in uterine discharges, milk, urine and semen. Unequivocal diagnosis depends on the isolation of Brucella from abortion material, udder secretions or from tissues removed at post-mortem. Brucella abortus, B. melitensis and B. suis are highly pathogenic for humans, and potentially contaminated tissues, cultures and materials must be handled under appropriate containment conditions.*

Detection of the agent: *Indication of Brucella is provided by the demonstration of Brucella-like organisms in abortion material or vaginal discharge using modified acid-fast staining, and is considered presumptive, especially if supported by serological tests. Polymerase chain reaction (PCR) methods are additional means for detection of the presence of Brucella DNA in a sample. Whenever possible, Brucella spp. should be isolated by culturing samples from uterine discharges, aborted fetuses, udder secretions or selected tissues, such as lymph nodes and male and female reproductive organs. Species and biovars can be identified by phage lysis, and by cultural, biochemical and serological tests. PCR can provide the basis of complementary identification and typing methods based on specific genomic sequences.*

Serological and cellular immunity tests: *Serological tests indicate exposure to Brucella species, but cannot identify the aetiological agent to the species level. The buffered Brucella antigen tests (rose bengal test and buffered plate agglutination test), the complement fixation test, the enzyme-linked immunosorbent assays (ELISA) or the fluorescence polarisation assay, are suitable tests for screening of herds/flocks and individual small ruminants, camelids and bovines (cattle and buffaloes). However, no single serological test is appropriate in each animal species and all epidemiological situations, and some of these tests are not adequate for diagnosing brucellosis in pigs. Therefore, the reactivity of samples that are positive in screening tests should be assessed using an established confirmatory or complementary strategy. The indirect ELISA or milk ring test performed on bulk milk samples is effective for screening and monitoring dairy cattle. The brucellin skin test can be used in unvaccinated ruminants, camels and swine as either a screening or a confirmatory herd test when positive serological reactors occur in the absence of obvious risk factors.*

Requirements for vaccines and diagnostic biologicals: *Brucella abortus strain 19 and B. melitensis strain Rev.1 remain the reference vaccines for the control of Brucella infections in cattle and in sheep and goats, respectively, with which any other vaccines should be compared. Both should be prepared from adequately derived seed cultures. The rough B. abortus strain RB51 vaccine has also become the official vaccine for prevention of B. abortus infection in cattle in some countries. No suitable vaccines exist for the control of Brucella infection in swine. Brucellin preparations must be free of smooth lipopolysaccharide, and antigens for serological tests must be prepared from smooth*

B. abortus strain 1119-3 or 99 and, in the case of indirect ELISA, from smooth B. melitensis strain 16M as well. Vaccines and brucellin preparations must comply with relevant standards.

A. INTRODUCTION

Brucellosis is the generic name used for the animal and human infections caused by several species of the genus *Brucella*, mainly *Brucella abortus, B. melitensis, B. suis* and *B. canis.* Infection of sheep with *B. ovis* is described separately in Chapter 3.8.7 *Ovine epididymitis* (*Brucella ovis*).

Causal pathogens: Genetic and immunological evidence indicates that all members of the *Brucella* genus are closely related. Nevertheless, based on relevant differences in host preference and epidemiology displayed by the major variants, as well as molecular evidence of genomic variation, the International Committee on Systematics of Prokaryotes, Subcommittee on the Taxonomy of *Brucella* took a clear position in 2005 on a return to pre-1986 *Brucella* taxonomic opinion; the consequences of this statement imply the re-approval of the six classical *Brucella* nomenspecies with their corresponding recognised biovars, although both opinions remain valid. The classical names related to the six *Brucella* nomenspecies are validly published in the Approved Lists of Bacterial Names, 1980, and the designated type strains are attached to these validly published names: *B. abortus, B. melitensis, B. suis, B. neotomae, B. ovis* and *B. canis*. The first three of these are subdivided into biovars based on cultural and serological properties (see Tables 2 and 3). Strains of *Brucella* have been isolated from marine mammals and classified into two new species: *B. ceti* and *B. pinnipedialis* (Foster *et al*., 2007). A new species, named *B. microti,* was also isolated from the common vole (*Microtus arvalis*) as well as from foxes, soil and frogs raised for human consumption in Europe (Scholz *et al*., 2008). Novel isolates from human breast implant infection, from baboons that had delivered stillborn offspring, and from foxes have also been described, although the natural reservoir of these isolates remains uncertain. While limited isolates of each new type have been described, they have been formally published as the tenth, eleventh, and twelfth *Brucella* species, *B. inopinata*, *B. papionis* and *B. vulpis* respectively (Scholz *et al*., 2010; 2016; Whatmore *et al*., 2014). Finally, various strains isolated from rodents, foxes reptiles, fish and frogs were characterised as atypical *Brucella* strains distinct from the currently described species. They have not yet been approved as new *Brucella* species.

Brucella is a member of the *Brucellaceae* family, in the order Rhizobiales, class Alphaproteobacteria. It shows close genetic relatedness to some plant pathogens and symbionts of the genera *Agrobacterium* and *Rhizobium*, as well as animal pathogens (*Bartonella*) and opportunistic or soil bacteria (e.g. *Ochrobactrum*).

1. Description of the disease

1.1. Infection with *Brucella* in cattle

Infection with *Brucella* in cattle is usually caused by biovars (bv.) of *Brucella abortus*. In some countries, particularly in southern Europe, Africa and western Asia, where cattle are kept in close association with sheep or goats, infection can also be caused by *B. melitensis* (Verger, 1985). Occasionally, *B. suis* may cause infections in cattle. The disease is global in distribution but a number of countries are considered free from both *B. abortus* and *B. melitensis*. For up-to-date information, consult WOAH WAHIS interface[1].

Young animals and non-pregnant females usually show no signs of the disease. Following infection with *B. abortus* or *B. melitensis*, pregnant adult females develop a placentitis usually resulting in abortion between the fifth and ninth month of pregnancy. Even in the absence of abortion, profuse excretion of the organism occurs in the placenta, fetal fluids and vaginal discharges. The mammary gland and associated lymph nodes may also be infected, and organisms may be excreted in the milk. Colostrum originating from infected dams is a source of infection in the newborn population. Subsequent pregnancies are usually carried to term, but uterine and mammary infection recurs, with reduced numbers of organisms in afterbirth products and milk. In acute infections, the organism is present in most major body lymph nodes. Adult male cattle may develop orchitis/epididymitis and brucellosis may be a cause of infertility in both sexes. *Brucella abortus* can be shed in semen, seminal fluid and urine. Hygromas, usually involving leg joints, are a common manifestation of brucellosis in some tropical countries and may be the only obvious indicator of infection; the hygroma fluid is often infected with *Brucella*.

1 https://www.woah.org/en/what-we-do/animal-health-and-welfare/disease-data-collection/

1.2. Infection with *Brucella* in sheep and goats

Infection with *Brucella* in sheep and goats (excluding *B. ovis* infection) is primarily caused by *B. melitensis*. Sporadic infections caused by *B. abortus* or *B. suis* have been observed in sheep and goats, but such cases are extremely rare. Infection with *Brucella* in sheep and goats is widespread although a number of countries are believed to be free from the agent. For up-to-date information, consult WOAH WAHIS interface. Pathologically and epidemiologically, *B. melitensis* infection in sheep and goats is very similar to *B. abortus* infection in cattle. In most circumstances, the primary routes of transmission of *Brucella* are the placenta, fetal fluids and vaginal discharges expelled by infected ewes and goats at and up to several months following abortion or parturition. Shedding of *Brucella* is also common in udder secretions and semen, and *Brucella* may be isolated from various tissues, such as lymph nodes from the head, spleen and organs associated with reproduction (uterus, epididymides and testes), and from arthritic lesions (Alton *et al*., 1988).

1.3. Infection with *Brucella* in pigs

Infection with *Brucella* in pigs is primarily caused by biovars 1, 2 or 3 of *B. suis*. Sporadic infections caused by *B. abortus* or *B. melitensis* have been also observed in pigs, but such cases are rare. The disease occurs in many countries where pigs are raised. Generally, the prevalence is low, but in some regions, such as South America and south-east Asia, the prevalence may be much higher. Porcine brucellosis may be a serious but presently unrecognised problem in some countries. *Brucella suis* bv. 1 infection has been reported from feral pigs in some of the southern states of the United States of America (USA), in parts of Australia and several other countries in Oceania. In these countries, a number of human infections have been reported from people who hunt and handle material taken from feral pigs. The disease is generally transmitted by consumption of feed contaminated by birth or abortion products and uterine discharges. Pigs will instinctively eat aborted fetuses and placental membranes. Transmission during copulation also occurs frequently, and *B. suis* excretion in semen has implications for those practising artificial insemination. In pigs, as in ruminants, after the initial bacteraemia, *B. suis* colonises the reproductive tract of either sex. In females, placentas and fetuses are invaded, while in males, invasion occurs in one or more of the following: testes, prostate, epididymides, seminal vesicles or bulbo–urethral glands. In males the lesions, which are most often unilateral, start with a hyperplasia that may progress to abscess formation; the final stage is characterised by sclerosis and atrophy. The most common manifestation of brucellosis in female pigs is abortion, occurring at any time during pregnancy, but most frequently between day 50 and 110 of gestation. Vaginal discharge is not often evident, and, in chronically infected herds, infertility rather than abortion is the most relevant clinical sign of the disease. In males, brucellosis is more likely to be persistent, with lesions in the genital tract often leading to interference with sexual activity, which can be temporary or permanent. The boar may excrete *Brucella* in the semen without any apparent abnormality in the sex organs or interference with sexual activity. In both sexes, arthritis may occur in various joints, there may be swollen joints and tendon sheaths, lameness and, occasionally, posterior paralysis or spondylitis. A significant proportion of both male and female pigs will recover from the infection, often within 6 months, but many will remain permanently infected (Olsen *et al*., 2012).

Infection caused by *B. suis* bv. 2 differs from infection caused by bv. 1 and bv. 3 in its host range, distribution, and in pathogenicity. Historically, the geographical distribution of *B. suis* bv. 2 has been in a broad range between Scandinavia and the Balkans. The prevalence in wild boars appears to be high throughout continental Europe (EFSA, 2009). In outbreaks in Europe, wild boars were implicated as the source of transmission of bv. 2 to outdoor reared pigs, and are considered as the main wild reservoir of this infection (EFSA, 2009). *Brucella suis* bv. 2 causes miliary lesions, particularly in reproductive tissues, that often become purulent. To date, *B. suis* bv. 2 has rarely been reported as the cause of human brucellosis. However, *B. suis* bv. 2 infections have been reported in immuno-compromised hunters, who had been extensively exposed through gutting or skinning boars or hares. Moreover, rare cases of *B. suis* bv. 2 infection without clinical signs have been reported in Europe in cattle or sheep exposed to infected wild boars.

1.4. Infection with *Brucella* in other domestic, captive–wild or wild species

Infection with *B. abortus* or *B. melitensis* has been reported in the one-humped camel (*Camelus dromedarius*) and the two-humped camel (*C. bactrianus*), as well as in the South American camelids: llama (*Lama glama*), alpaca (*Vicugna pacos*), guanaco (*Lama guanicoe*), and vicuña (*Vicugna vicugna*), and is related to contact with large and small ruminants infected with *B. abortus* or *B. melitensis.*

In addition, brucellosis has been observed in the domestic buffalo (*Bubalus bubalis*), American and European bison (*Bison bison* and *B. bonasus*, respectively), yak (*Bos grunniens),* elk/wapiti (*Cervus canadensis, sika deer* (*C. nippon*), African buffalo (*Syncerus caffer*) and various antelope species. The clinical manifestations of brucellosis in these animals are similar to those seen in cattle, sheep and goats.

Brucella melitensis infection in wild ruminants may occur when these species are in close contact with sheep and goats in enzootic areas. The manifestations of brucellosis in these animals are similar to those in cattle or sheep and goats. However, in several wild ruminant species (e.g. chamois [*Rupicapra rupicapra*], Alpine ibex [*Capra ibex*] and the Iberian wild goat [*Capra pyrenaica*]), purulent or calcified arthritis and orchitis as well as uveitis and neurological signs have been reported. These species are considered as dead-end carriers, and the disease usually disappears naturally as soon as *Brucella* infection has been eradicated from domestic livestock, unless anthropogenic effects take place. Nevertheless three reservoirs are currently described in wild ruminants: *B. abortus* in bison in the Yellowstone area of North America, *B. melitensis* in alpine ibex and *B. abortus* in wood bison in Wood Buffalo National Park in Canada. There have also been sporadic reports of *B. melitensis* isolation from dogs, especially from contact with infected sheep or goats, or ingestion of placenta or aborted fetuses.

There are two different types of epidemiological situation with regard to *B. suis* infection in other non-porcine species. In the first case, *B. suis* infection occurs in animals that are not the natural host of the particular infection through the ingestion of contaminated materials or by co-habitation with infected natural hosts. For example, Arctic foxes and wolves may contract *B. suis* bv. 4 from reindeer; dogs and rodents, such as rats and mice, may acquire other *B. suis* biovars by cohabitation with infected hosts; cattle and horses may become infected by cohabitation or interaction with infected swine. The infecting bacteria are invariably the well-defined biovars of the natural host species. In the second case, wildlife species are natural hosts for *B. suis* or *B. suis*-like infections. One example is the so-called murine brucellosis of the Commonwealth of Independent States (CIS) and the Baltic countries, where small rodents are infected with *B. suis* bv. 5.

In addition to wild boar, the European hare (*Lepus europaeus*) is also considered to be a reservoir for *B. suis* bv. 2 and has been implicated as a possible source of transmission to domestic livestock. The disease in the European hare is characterised by the formation of nodules, varying in size from that of a millet seed to a cherry or even larger; these often become purulent. Such nodules may occur in almost any location, sometimes subcutaneously or intramuscularly, in the spleen, liver or lung and in the reproductive organs of either sex. The body condition of the hare may be unaffected. Other species may also become infected by cohabitation with *B. suis* bv. 2 infected swine, wild boars or hares. Gutting or skinning wild boars in cattle sheds could be a route of transmission to cattle.

Brucella suis bv. 4 causes a serious zoonotic disease in wild or domesticated reindeer or caribou (*Rangifer tarandus* and its various subspecies) throughout the Arctic region, including Siberia, Canada and Alaska. *Rangifer tarandus* is very susceptible to *B. suis* infection, which causes fever, depression and various local signs, such as abortion, retained placentas, metritis, sometimes with blood-stained discharge, mastitis, bursitis and orchitis. Transmission to humans may be by direct contact or through consumption of raw milk and other inadequately heated products from reindeer, bone marrow in particular.

1.5. Zoonotic risk and biosafety requirements

Some *Brucella* species, most notably *B. melitensis, B. abortus, B. suis* and, probably to a lesser extent *B. canis* are readily transmissible to humans, causing acute febrile illness – undulant fever – which may progress to a more chronic form and can also produce serious complications affecting the musculo-skeletal, cardiovascular, and central nervous systems. Precautions should be taken to prevent human infection. Infection is acquired by the oral, respiratory, or conjunctival routes. Ingestion of raw milk products constitutes the main risk to the general public where the disease is endemic. There is an occupational risk to veterinarians, abattoir workers and farmers who handle infected animals/carcasses and aborted fetuses or placentas. Brucellosis is also one of the most easily acquired laboratory infections, and all laboratory manipulations with live cultures or potentially infected/contaminated material must be performed at an appropriate biosafety and containment level determined by biorisk analysis (see Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*). Specific recommendations have been made for the biosafety precautions to be observed with *Brucella*-infected materials (for further details see Alton *et al*., 1988;

Joint FAO/WHO Expert Committee on Brucellosis, 1986; WHO, 1953; WHO, 2004; Chapter 1.1.3 *Transport of biological materials*).

B. DIAGNOSTIC TECHNIQUES

***Table 1. Test methods available for the diagnosis of infection with* Brucella abortus, melitensis *or* suis**

Method	Purpose					
	Population freedom from infection	Individual animal freedom from infection[a]	Contribute to eradication policies[b]	Confirmation of suspect or clinical cases[c]	Herd/flock prevalence of infection – surveillance	Immune status in individual animals or populations post-vaccination
Detection of the agent						
Staining methods	–	–	–	+	–	–
Culture	–	–	–	+++	–	–
PCR[d]	–	–	–	+/++	–	–
Detection of immune response						
BBAT (RBT or BPAT)	+++	++	+++	+	+++	–
FPA	++	++	+	++	++	–
CFT	++	++	+++	++	+++	–
I-ELISA	+++	++	+++	++	+++	–
C-ELISA	++	+	+	+	++	–
BST	++	–	+	+++	++	–
SAT	++	+	+	–	+	–
NH and cytosol protein-based tests[e]	–	–	+	++	–	–
Bulk milk tests[f] Milk I-ELISA or Milk ring-test	+++	–	+++	+	+++	–

Key: +++ = recommended for this purpose; ++ recommended but has limitations;
+ = suitable in very limited circumstances; – = not appropriate for this purpose.
PCR = polymerase chain reaction; BBAT = buffered *Brucella* antigen tests (i.e. RBT [rose bengal test] and BPAT [buffered plate agglutination test]); FPA = fluorescence polarisation assay; CFT = complement fixation test; I- or C-ELISA = indirect/competitive enzyme-linked immunosorbent assay; BST = brucellin skin test; SAT = serum agglutination test; NH = native hapten

[a]This applies only to herds/flocks, countries or zones free from infection with *Brucella*.

[b]To increase the efficiency of eradication policies in infected herds/flocks, it is recommended to associate tests in parallel so as to increase the sensitivity of the diagnosis, i.e. two serological tests at least, e.g. BBAT or FPA and CFT or I-ELISA. The sensitivity is further increased by parallel testing by both serology and BST.

[c]In low-prevalence or almost-free zones, the predictive value of positive results to serological tests may be very low. In such situations, agent identification is usually needed to confirm clinical cases.
In infected herds/flocks, a positive result to any serological test may be considered as confirmation of a clinical case. Any reactor in any serological test should be considered to be infected even in the absence of clinical signs.
In low-prevalence or almost-free zones, singleton serological reactors may be confirmed by culture (or PCR) or BST.
In free countries or zones, suspect animals are those positive to both a screening and a confirmatory serological test (tests in series) and may be confirmed by culture (or PCR) and/or BST.

[d]False-positive results may occur.

[e]In zones where subcutaneous S19 or Rev.1 vaccination is practised, this test may help in differentiating antibodies due to vaccination from those due to infection.

[f]Dairy cattle only.

All cases of abortion as well as orchitis in cattle, sheep and goats, camels and pigs, should be considered as suspected brucellosis and should be investigated through the herd/flock history and submission of specimens for laboratory testing. The clinical signs are not pathognomonic and unequivocal diagnosis of *Brucella* infections can be made only by the isolation and identification of *Brucella*, but in situations where bacteriological examination is not practicable, diagnosis must be based on molecular or immunological methods.

1. Detection of the agent

Classically a bacterial culture is identified as *Brucella* by growth characteristics (see Section B.1.3 *Identification and typing*) although unequivocal identification as *Brucella* is now possible through various molecular approaches.

All samples from suspect cases should be cooled (4°C) immediately after they are taken, and transported to the laboratory by the most rapid means. If they are to spend more than 12 hours in transit, all samples apart from vaginal swabs, should be frozen (–20°C). On arrival at the laboratory, samples that are not to be cultured immediately should be frozen (Alton *et al*., 1988). In all cases, the shorter the shipment and storage time, the higher is the probability of *Brucella* isolation, especially in cases where the initial amount of *Brucella* is low in the sample. No specific transport medium has been demonstrated to improve *Brucella* survival in animal samples.

1.1. Staining methods

Brucella are coccobacilli or short rods measuring from 0.6 to 1.5 μm long and from 0.5 to 0.7 μm wide. They are usually arranged singly, and less frequently in pairs or small groups. The morphology of *Brucella* is fairly constant, except in old cultures where pleomorphic forms may be evident. *Brucella* are nonmotile. They do not form spores; pili or true capsules are not produced. *Brucella* are Gram negative and usually do not show bipolar staining. They are resistant to decolourisation by weak acids and thus stain red by the Stamp's modification of the Ziehl–Neelsen's method (Alton *et al*., 1988). With this method, in smears of organs or biological fluids previously fixed with heat or ethanol, *Brucella* organisms stain red against a blue background. A fluorochrome or peroxidase-labelled antibody conjugate-based technique could also be used. The presence of intracellular, weakly acid-fast organisms of *Brucella* morphology or immuno-specifically stained organisms is presumptive evidence of brucellosis. However, these methods are not feasible or have a low sensitivity in milk and dairy products where *Brucella* are often present in small numbers, and interpretation is frequently impeded by the presence of fat globules. Care must be taken as well in the interpretation of positive results in the Stamp's method because other organisms that cause abortions, e.g. *Chlamydia abortus* or *Coxiella burnetii,* may be difficult to differentiate from *Brucella* organisms in these preparations. The results, whether positive or negative, should be confirmed by culture.

Polymerase chain reaction (PCR) methods can also be used to demonstrate the agent in various biological samples (Bricker, 2002; Whatmore & Gopaul, 2011), but the sensitivity of these approaches may be low with respect to classical bacteriology because of limitations around sample volume. Molecular tests may detect infection where poor sample storage means bacteria are no longer viable.

1.2. Collection of samples and culture

Bacteriological isolation is slow, expensive and cumbersome, but it should be performed whenever possible to confirm the disease and to determine the *Brucella* species involved. It also enables emerging epidemiological approaches such as high throughput sequencing to be applied. Although often considered not sensitive, it can be very effective when the type and number of samples, their adequate storage, amount seeded and the culture media used are optimised.

1.2.1. Basal media

Direct isolation and culture of *Brucella* are usually performed on solid media. This is generally the most satisfactory method as it enables the developing colonies to be isolated and recognised clearly. Such media also limit the establishment of non-smooth mutants and excessive development of contaminants. However, the use of liquid media may be recommended for voluminous samples or for the purpose of enrichment. A wide range of commercial dehydrated basal media is available, e.g. *Brucella* medium base, tryptose (or trypticase)–soy agar (TSA). The addition of 2–5% bovine or equine serum is necessary for the growth of strains such as *B. abortus* bv. 2, and many laboratories systematically add serum to basal media, such as blood agar base or Columbia agar, with excellent results. Other satisfactory media, such as serum–dextrose agar (SDA) or glycerol–dextrose agar, can be used (Alton *et al*., 1988). SDA is usually preferred for

observation of colonial morphology. A non-selective, biphasic medium, known as Castañeda's medium, is recommended for the isolation of *Brucella* from blood and other body fluids or milk, where enrichment culture is advised. Castañeda's medium is used because brucellae tend to dissociate in broth medium, interfering with biotyping by conventional bacteriological techniques.

1.2.2. Selective media

All the basal media mentioned above can be used for the preparation of selective media. Appropriate antibiotics are added to suppress the growth of organisms other than *Brucella*.

The most widely used selective medium is the modified Farrell's medium (FM) (Stack *et al*., 2002), added to 1 litre of agar: polymyxin B sulphate (5000 units = 5 mg); bacitracin (25,000 units = 25 mg); natamycin (50 mg); nalidixic acid (5 mg); nystatin (100,000 units); vancomycin (20 mg). A corresponding freeze-dried antibiotic supplement is available commercially. However, nalidixic acid and bacitracin, at the concentration used in FM, have inhibitory effects on some *B. abortus*, *B. melitensis* and *B. suis* strains. Accordingly, the simultaneous use of FM and the less selective Thayer–Martin's modified (mTM) culture media has been considered the strategy of choice for *Brucella* primary isolation from field veterinary samples. However, the mTM is not translucent because of the haemoglobin contained as a basal component, being thus unsuitable for the direct observation of colonial morphology, probably the most practical procedure for the presumptive identification of *Brucella* (Alton *et al*., 1988).

A selective and translucent culture medium (named CITA) was formulated by De Miguel *et al*. (2011). For its preparation, blood agar base is used as a basal component, supplemented with 5% sterile calf serum and containing vancomycin (20 mg/litre), colistin methanesulfonate (7.5 mg/litre), nitrofurantoin (10 mg/litre), nystatin (100,000 International Units [IU)]/litre), and amphotericin B (4 mg/litre). This antibiotic mixture can be prepared as follows: weigh vancomycin, colistin and nystatin in the same 50 ml sterile container, then rehydrate the mixture with 10 ml of a 1:1 solution of absolute methanol in sterile purified water. Weigh then nitrofurantoin in a sterile tube and dissolve it with 1 ml of 0.1 M NaOH solution (sterilised previously by filtration through a 0.22 μm filter). Finally, weigh 10 mg of amphotericin B in a 20 ml sterile container and dissolve with 1 ml dimethyl sulphoxide. Once fully dissolved (5–10 minutes are required), add 9 ml of 10 mM sterile phosphate-buffered saline (PBS) (pH=7.2 ± 0.2). The final concentration of amphotericin B would be 1 mg/ml; a total of 4 ml of this solution are required for 1 litre of medium. The remaining Amphotericin B suspension can be kept at 5°C ± 3°C for several days for further uses. This CITA medium inhibits most contaminant microorganisms but allows simultaneously the growth of all *Brucella* species and is more sensitive than both mTM and Farrell's media for isolating all smooth *Brucella* species from field samples, being thus the selective medium of choice for overall *Brucella* isolation, although the maximal diagnostic sensitivity is obtained using both FM and CITA simultaneously (De Miguel *et al*., 2011).

A modified *Brucella* selective medium (named MBS) has been developed to select *B. abortus* strains, including the RB51 vaccine strain more effectively than previously described media but needs further validation studies to confirm performance (Her *et al*., 2010).

Contrary to the situation with several *B. abortus* biovars as well as *B. ovis*, the growth of *B. melitensis* or *B. suis* is not dependent on an incubating atmosphere containing 5–10% CO_2 (Table 2), but such a CO_2 enriched-atmosphere is optimal for the culture of all *Brucella*.

As the number of *Brucella* organisms is likely to be lower in milk, colostrum and some tissue samples than in abortion material, enrichment can be advisable. In the case of milk, results can be improved by centrifugation and culture from both the cream and the pellet, but strict safety measures should be implemented in this case to avoid aerosols. A more practical way to increase the sensitivity of milk culture while avoiding the risks of centrifugation is increasing the number of both FM and CITA culture plates per milk sample tested (two plates per udder quarter should be a minimum), each plate being inoculated with ca. 0.5 ml of milk. Enrichment can be carried out in liquid medium consisting of serum–dextrose broth, tryptose broth or trypticase–soy broth (TSB) or *Brucella* broth supplemented with an antibiotic mixture of at least amphotericin B (1 μg/ml), and vancomycin (20 μg/ml) (all final concentrations). The enrichment medium should be incubated at 37°C ± 2°C in air supplemented with 5–10% (v/v) CO_2 for up to 6 weeks, with weekly subcultures on to solid FM and CITA selective media. If preferred, a biphasic system of

solid and liquid selective medium in the same bottle (Castañeda's method) may be used to minimise subculture. A selective biphasic medium composed of the basal Castañeda's medium with the addition of the following antibiotics to the liquid phase, is sometimes recommended for isolation of *Brucella* in milk (quantities are per litre of medium): polymyxin B (sulphate) (6000 units = 6 mg); bacitracin (25,000 units = 25 mg); natamycin (50 mg); nalidixic acid (5 mg); amphotericin B (1 mg); vancomycin (20 mg); D-cycloserine (100 mg).

ND Not determined

All culture media used should be subjected to quality control with the reference strains to show that it performs properly. The use of a small inoculum of fastidious strains, such as *B. abortus* bv. 2, *B. ovis* or *B. suis* bv. 2, is preferred.

On suitable solid media, colonies of *B. abortus*, *B. melitensis* and *B. suis* can be clearly visible after a 3- to 4-day incubation period. After 4-days' incubation, *Brucella* colonies are round, 1–2 mm in diameter, with smooth margins. They are translucent and a pale honey colour when plates are viewed through a transparent medium. When viewed from above, colonies appear convex and pearly white. Later, colonies become larger and slightly darker. Smooth (S) *Brucella* cultures have a tendency to undergo variation during growth, especially with subcultures, and to dissociate to rough (R) forms. Colonies are then much less transparent, have a more granular, dull surface, and range in colour from matt white to brown in reflected or transmitted light. Checking for dissociation is easily tested by crystal violet staining: rough colonies stain red/violet and smooth colonies do not uptake dye or stain pale yellow. If the colonies are smooth, they should be checked against antiserum to smooth *Brucella*, or, if available, against anti-A and -M monospecific sera. In the case of non-smooth colonies, isolates should be checked with antiserum to *Brucella* R antigen. Changes in the colonial morphology are generally associated with changes in virulence, serological properties or phage sensitivity. Typical colonial morphology and positive agglutination with specific *Brucella* antiserum, followed by the oxidase and urease tests (see Tables 2 and 3), allow preliminary identification of the isolate as *Brucella*. However, it is recommended that subsequent confirmation and typing is performed by a reference laboratory.

1.2.3. Collection and culture of samples

For the diagnosis of animal brucellosis by cultural examination, the choice of samples usually depends on the clinical signs observed. The most valuable samples include vaginal secretions (swabs), aborted fetuses (stomach contents, spleen and lung), fetal membranes, and milk, semen and arthritis or hygroma fluids. From animal carcasses, the preferred tissues for culture are those of the reticulo-endothelial system (i.e. head, mammary and genital lymph nodes and spleen), the pregnant or early post-parturient uterus, and the udder. Growth normally appears after 3–4 days, but cultures should not be discarded as negative until 7–10 days have elapsed. When *Brucella* are present in small numbers, isolation from such samples is very unlikely so enrichment culture is advised and molecular detection may be considered as a parallel complementary diagnostic to increase sensitivity.

1.2.3.1. Tissues

Samples are removed aseptically with sterile instruments. The tissue samples are prepared by removal of extraneous material (e.g. fat), cut into small pieces, and macerated using a paddle blender or tissue grinder with a small amount of sterile PBS, before being inoculated on to solid media or enrichment broth.

1.2.3.2. Vaginal discharge

A vaginal swab taken after abortion or parturition is an excellent source for the recovery of *Brucella* and far less risky for the personnel than abortion material. The swab is then streaked directly onto solid media.

1.2.3.3. Milk

Milk culture can be particularly valuable for screening individual animals or herds for the presence of *Brucella*. Samples of milk must be collected cleanly after washing, drying and disinfecting the teats. Personal protection must be worn throughout. It is essential that samples should contain milk from all quarters, and 10–20 ml of milk should be taken from each teat, changing or disinfecting the gloves from one animal to the next to avoid cross-contamination of the samples. The first streams are discarded and the sample is milked directly into a sterile vessel or container. Care must be taken to avoid contact between the milk and the milker's hands. The milk can be centrifuged and the cream and deposit are spread on solid selective medium, either separately or mixed or streaked directly as indicated above. If *Brucella* are present in bulk milk samples, their numbers are usually low, and isolation from such samples is very unlikely.

1.2.3.4. Dairy products

Dairy products, such as cheese, should be cultured on the media described above. As these materials are likely to contain small numbers of organisms, enrichment culture with selective media is advised. Samples need to be carefully homogenised before culture, after they have been ground in a tissue grinder or macerated and pounded in a 'paddle blender or an electric blender with an appropriate volume (avoiding over-dilution) of sterile PBS. Superficial strata (rind and underlying parts) and the core of the product should be cultured. As brucellae grow, survive or disappear quite rapidly, their distribution throughout the different parts of the product varies according to the local physico-chemical conditions linked to specific process technologies.

1.2.3.5. Arthritis/hygroma fluids – abscesses content

Such samples must be collected aseptically and spread directly on solid selective media.

All the above samples should be cooled (4–10°C) immediately after sampling and transported to the laboratory in the fastest way. Otherwise, the samples should be frozen to avoid viability losses. On arrival at the laboratory, milk and tissue samples and other biological liquids should be frozen if they are not to be cultured immediately.

1.2.3.6. Blood culture

Culture from blood can be attempted although bacteraemia in livestock animals is generally considered short lived or intermittent so the approach is not widely used. Direct culturing of anti-coagulant treated blood (sodium citrate or heparin, except EDTA [ethylene diamine tetra-acetic acid]) may be performed on selective or non-selective agar to obtain results in a shorter time (4–7 days; Alton, 1988). Alternatively an appropriate non-selective media, such as TSB, can be inoculated with blood and subcultured at weekly intervals onto selective Farrell's media for up to 4 weeks.

1.2.3.7. Animal passage

Although used historically, use of laboratory animals should be avoided unless absolutely necessary, but may sometimes provide the only means of detecting the presence of *Brucella,* especially when samples have been shown to be heavily contaminated or are likely to contain a low number of *Brucella* organisms. Animal inoculation may be intravenously or intraperitoneally in mice or intra-muscularly, subcutaneously or intraperitoneally in guinea-pigs. This work must be carried out under appropriate biosafety conditions as outlined in chapter 1.1.4. The spleens of inoculated animals are cultured at 7 days (mice) or 3–6 weeks (guinea-pigs) after inoculation. Serum samples can be collected by intra-cardiac puncture before necropsy from guinea-pigs and subjected to buffered *Brucella* antigen tests (BBAT); a positive serological result is highly suggestive of brucellosis (Alton *et al*., 1988).

1.3. Identification and typing

Any colonies showing the characteristic *Brucella* morphology should be examined using a Gram-stained-smear. As the serological properties, dyes and phage sensitivity are usually altered in the non-smooth phases, attention to the colonial morphology is essential in the typing tests described below. The recommended methods for observing colonial morphology are Henry's method by obliquely reflected light, the acriflavine test described by Braun & Bonestell, or White & Wilson's crystal violet method of staining colonies (Alton *et al*., 1988).

Identification of *Brucella* organisms to species and biovar level can be carried out by a combination of the following tests: organism morphology after Gram or Stamp's staining, direct observation of colonial morphology, growth characteristics, urease and oxidase tests, and the slide agglutination test with a polyclonal anti-*Brucella* serum. Species and biovar identification requires elaborate tests (such as phage lysis and agglutination with anti-A, -M or -R monospecific sera), the performance of which should be left to reference laboratories with accredited expertise in these methods. The simultaneous use of several phages e.g. Tbilisi (Tb), Weybridge (Wb), Izatnagar$_1$ (Iz$_1$) and R/C provides a phage-typing system that, in experienced hands, allows a practical identification of the *Brucella* species. However, several characteristics, for example added CO_2 requirement for growth, production of H_2S (detected by lead

acetate papers), and growth in the presence of basic fuchsin and thionin, are revealed by routine tests that can be performed in moderately equipped non-specialised laboratories (see Tables 2 and 3). While the technique remains useful particularly at the species level, the value of the biovar designations as epidemiological markers is increasingly questioned as, notably in the case of *B. melitensis* and some *B. abortus* biovars, molecular evidence has shown biovars do not correspond to meaningful genetic divisions.

MALDI-TOF (matrix assisted laser desorption ionisation time of flight) is increasingly used in diagnostic microbiology and has been applied to identification of *Brucella*. While application of MALDI-TOF appears effective for genus identification the close genetic relationship among *Brucella* species, and limitations in commercial database coverage, has not yet enabled robust and unambiguous discrimination of *Brucella* species.

For the maintenance of *B. abortus, B. melitensis* or *B. suis* strains as well as for sending them to a reference laboratory for typing, it is essential that only smooth colonies be selected. Cultures may be maintained for short periods at 5°C ± 3°C, but for longer periods they should be lyophilised or stored in a screw-capped tube at a temperature ≤ –16°C in tryptose broth with 15% (v/v) glycerol. For shipment, cultures should be lyophilised and sealed in ampoules packed in screw-capped canisters or subcultured onto appropriate nutrient agar slopes contained in screw-capped bottles. The strains could also be sent suspended in transport media (e.g. Amies), but this could cause dissociation.

For transporting *Brucella* cultures, the caps of the bottles or canisters should be screwed tightly down and sealed with PVC (polyvinyl chloride) tapes. Bottles should be wrapped in absorbent paper or cotton wool, sealed in polyethylene bags and packed into a rigid container (triple packaging) in accordance with the requirements of the International Air Transport Association (IATA) for shipping dangerous goods (IATA, 2021). These regulations are summarised in Chapter 1.1.2 *Collection, submission and storage of diagnostic specimens* and Chapter 1.1.3 *Transport of biological materials*, and they must be followed.

1.4. Nucleic acid recognition methods

The PCR, including the real-time format, provides an additional means of detection and identification of *Brucella* sp. (Bricker, 2002; Lopez-Goni *et al*., 2011; Ocampo-Sosa *et al*., 2005; Whatmore & Gopaul, 2011). Despite the high degree of DNA homology within the genus *Brucella*, several historical molecular methods including PCR, PCR restriction fragment length polymorphism (RFLP) and Southern blot, allowed, to a certain extent, the differentiation of *Brucella* species and some of their biovars (for a review see Bricker, 2002; Moreno *et al*., 2002; Whatmore & Gopaul, 2011).

The first species-specific multiplex PCR assay for the differentiation of *Brucella* was described by Bricker & Halling (1994). The assay, named AMOS-PCR, was based on the polymorphism arising from species-specific localisation of the insertion sequence IS711 in the *Brucella* chromosome, and comprised five oligonucleotide primers that could identify without differentiating *B. abortus* bv. 1, 2 and 4 but could not identify *B. abortus* bv. 3, 5, 6, and 9. Modifications to the assay have been introduced over time to improve performance, and additional strain-specific primers were incorporated for identification of the *B. abortus* vaccine strains, and other biovars and species (Ocampo-Sosa *et al*., 2005). A multiplex PCR assay (Bruce-ladder) has been proposed for rapid and simple one-step identification of *Brucella* (Lopez-Goni *et al*., 2011). The major advantage of this assay over previously described PCRs is that it can identify and differentiate in a single step most *Brucella* species as well as the vaccine strains *B. abortus* strain 19 (S19), *B. abortus* RB51 and *B. melitensis* Rev.1. In contrast to other PCRs, Bruce-ladder is also able to detect DNA from *B. neotomae, B. pinnipedialis* and *B. ceti*. An update to the original Bruce-ladder PCR protocol has been described. This updated version (Bruce-ladder v2.0), that has been validated in several laboratories, is also able to discriminate between *B. suis* and *B. canis*, and allows the differentiation of *B. microti* as does a modification reported by Kang *et al.* (2011). Similarly, another updated multiplex PCR assay (Suis-ladder), has been developed for fast and accurate identification of *B. suis* strains at the biovar level (Lopez-Goni *et al*., 2011).

Alternative approaches allowing identification of all *Brucella* species, *B. suis* biovars and vaccine strains based on single nucleotide polymorphism (SNP) discrimination by either primer extension or real-time PCR or the ligase-chain-reaction have been described. These tests are rapid, simple, unambiguous, and based on a robust population genetic analysis that helps ensure the species/biovar specificity of markers used (Whatmore & Gopaul, 2011).

A number of other methods adding useful epidemiological information have also been described and are widely used. These include multilocus sequencing schemes (Whatmore & Foster, 2021) and several typing schemes based on the use of MLVA (multiple locus variable number of tandem repeats analysis) (Le Fleche *et al*., 2006; Scholz & Vergnaud, 2013; Whatmore & Foster, 2021). Depending on the particular markers chosen, these methods allow isolates to be identified at species level and provide epidemiological information at the subspecies level. Finally, whole genome sequence-based approaches are rapidly becoming tools for routine surveillance and outbreak detection for several infectious diseases including brucellosis. Through various analytical approaches being developed, including SNP-based approaches or gene-by-gene comparison through core-genome multilocus sequence typing (cgMLST), it is already clear that whole genome sequence approaches will offer the ultimate level of epidemiological precision. These tools will become more widely accessible with time and ultimately greatly inform understanding of local and international brucellosis epidemiology.

1.5. Identification of vaccine strains

Vaccine strains *B. abortus* S19, *B. melitensis* Rev.1 and *B. abortus* RB51 may be identified using specific PCRs (Kang *et al*., 2011; Lopez-Goňi *et al*., 2011), or by their growth characteristics in culture.

Brucella abortus S19 has the typical properties of a bv. 1 strain of *B. abortus*, but does not require CO_2, does not grow in the presence of benzyl-penicillin (3 μg/ml = 5 IU/ml), thionin blue (2 μg/ml), or i-erythritol (1 mg/ml) (all final concentrations), and presents a high L-glutamate use (Alton *et al*., 1988).

Brucella melitensis strain Rev.1 has the typical properties of a bv. 1 strain of *B. melitensis*, but develops smaller colonies on solid media, does not grow in the presence of basic fuchsin, thionin (both at 20 μg/ml) or benzyl-penicillin (3 μg/ml), but does grow in the presence of streptomycin at 2.5 or 5 μg/ml (5 IU/ml) (Alton *et al*., 1988).

Brucella abortus strain RB51 can be distinguished from its *B. abortus* biovar 1 smooth counterparts by its rough morphology and growth in presence of rifampicin (250 μg per ml of media).

2. Serological tests

No single serological test is appropriate in all epidemiological situations and all animal species; all tests have limitations especially when testing individual animals. Consideration should be given to all factors that impact on the relevance of the test method and test results to a specific diagnostic interpretation or application. In epidemiological units where vaccination with smooth *Brucella* is practised, and depending on the vaccination method (dose/route) used, positive serological reactions may be expected among the vaccinated animals because of antibodies cross-reacting with wild strain infection. Moreover, a number of bacteria, in particular *Yersinia enterocolitica* O:9, may induce antibody responses that cause false positive serological reactions (FPSR) in brucellosis tests, impeding accurate serological diagnosis. FPSR may occur in all animal species at variable rates according to the time and the region.

The serum agglutination test (SAT) is generally regarded as being unsatisfactory for the purposes of international trade. The complement fixation test (CFT) is more specific than the SAT, and has also a standardised system of unitage, but can be impacted by anti-complementary activity. The diagnostic performance characteristics of some enzyme-linked immunosorbent assays (ELISAs) and the fluorescence polarisation assay (FPA) are comparable with or better than that of the CFT, and as they are technically simpler to perform and more robust, their use may be preferred. The diagnostic performance of these tests has been compared in cattle, small ruminants and swine.

For the control of brucellosis at the national or local level, BBATs (the rose bengal test [RBT] and the buffered plate agglutination test [BPAT]), ELISA and FPA, are considered as suitable screening tests. Depending on the purpose of testing, positive reactors could be retested using a suitable confirmatory or complementary method.

In other species, for example, buffaloes (*Bubalus bubalis*), American and European bison (*Bison bison, Bison bonasus*), yak (*Bos grunniens*), elk/wapiti (*Cervus elaphus*), camels (*Camelus bactrianus* and *C. dromedarius*), and South American camelids, *Brucella* sp. infection follows a course similar to that in cattle. The same serological procedures may be used for these animals, but each test should be validated for its fitness in the corresponding animal species.

2.1. Reference sera

WOAH reference standards are those against which all other standards are compared and standardised. These reference standards are all available to national reference laboratories and should be used to establish secondary or national standards against which working standards can be prepared and used in the diagnostic laboratory for daily routine use.

These sera have been developed and designated by WOAH as International Standard Sera[2]. The use of these reagents promotes international harmonisation of diagnostic testing and antigen standardisation:

i) For RBT, CFT, SAT and milk ring test (MRT), WOAH International Standard Serum (WOAHISS, previously named the WHO Second International standard anti-Brucella abortus Serum; WHO, 1953) is used. This serum is of bovine origin and contains 1000 IU (SAT) and 1000 ICFTU (international complement fixation test units).

ii) For indirect ELISA (I-ELISA), competitive or blocking ELISA (C-ELISA) and FPA in cattle, three WOAH ELISA Standard Sera are available for use. These are also of bovine origin and consist of a strong positive ($WOAHELISA_{SP}SS$), a weak positive ($WOAHELISA_{WP}SS$) and a negative ($WOAHELISA_{N}SS$) standard.

iii) For I-ELISA, C-ELISA and FPA in sheep and goats, the International standard anti-*Brucella melitensis* Serum (ISaBmS) is used (McGiven *et al*., 2011).

iv) For I-ELISA, C-ELISA and FPA in pigs, there is no WOAH International Standard serum available at present. However, an EU standard for porcine I-ELISA and C-ELISA, EUPigBSS, is available[3].

2.2. Production of antigens

Brucella abortus strain 99 (Weybridge) (S99)[3] or *B. abortus* strain 1119-3 (USDA) (S1119-3)[4] should always be used for the production of antigens for the BBATs, SAT, CFT and FPA. These *B. abortus* strains can be also used as a source of soluble antigen extracts (smooth lipopolysaccharide [S-LPS] or O-polysaccharide [OPS]) for the ELISAs or the Native Hapten tests, but *B. melitensis* strain 16M is also suitable for such a purpose. It should be emphasised that antigen made with any of the two *B. abortus* or *B. melitensis* 16M strains is used to test for any infections due to smooth *Brucella* species.

The strains must be completely smooth and should not auto-agglutinate in saline and 0.1% (w/v) acriflavine. They must be pure cultures and conform to the characteristics of CO_2-independent strains of *B. abortus* bv. 1 or *B. melitensis* bv. 1. The original seed cultures should be propagated to produce a seed lot that must conform to the properties of these strains, and should be preserved by lyophilisation or by freezing in liquid nitrogen.

For antigen production, the seed culture is used to inoculate a number of potato-infusion agar slopes that are then incubated at 37°C ± 2°C for 48 hours. SDA and TSA, to which 5% equine or new-born calf serum or 0.1% yeast extract may be added, are satisfactory solid media provided a suitable seed is used as recommended above. The growth is checked for purity, resuspended in sterile PBS, pH 6.4, and used to seed layers of potato-infusion agar or glycerol-dextrose agar in Roux flasks. These are then incubated at 37°C ± 2°C for 72 hours with the inoculated surface facing down. Each flask is checked for purity by Gram staining samples of the growth, and the organisms are harvested by adding 50–60 ml phenol saline (0.5% phenol in 0.85% sodium chloride solution) to each flask. The flasks are gently agitated, the suspension is decanted, and the organisms are killed by heating at 80°C for 90 minutes. Following a viability check, the antigen is stored at 5°C ± 3°C.

Alternatively, the cells may be produced by batch or continuous culture in a fermenter, using a liquid medium containing (per litre of purified water) D-glucose (30 g), a high-grade peptone (30 g), yeast extract (Difco) (10 g), sodium dihydrogen phosphate (9 g) and disodium hydrogen phosphate (3.3 g). The initial pH is 6.6 (± 0.2), but this tends to rise to pH 7.2 (± 0.2) during the growth cycle. Care should be taken to check batches of peptone and yeast extract for capacity to produce good growth without formation of abnormal or dissociated cells. Vigorous aeration and stirring is required during growth, and adjustment

2 Obtainable from the WOAH Reference Laboratory for brucellosis in the United Kingdom (see online list of WOAH Reference Laboratories for address: https://www.woah.org/en/what-we-offer/expertise-network/reference-laboratories/#ui-id-3).

3 Obtainable from the WOAH Reference Laboratory for brucellosis in France.

4 Obtainable from the United States Department of Agriculture (USDA), National Veterinary Services Laboratories (NVSL) 1800 Dayton Road, Ames, Iowa, United States of America.

to pH 7.2 (± 0.2) by the addition of sterile 0.1 M HCl may be necessary. The seed inoculum is prepared as described above. The culture is incubated at 37°C ± 2°C for 48 hours. Continuous culture runs can be operated for much longer periods, but more skill is required to maintain them. In-process checks should be made on the growth from either solid or liquid medium to ensure purity, an adequate viable count and freedom from dissociation to rough forms. Cells for use in the preparation of all antigens should be checked for purity and smoothness at the harvesting stage.

The culture is harvested by centrifugation to deposit the organisms, which are resuspended in phenol saline. The organisms are killed by heating at 80°C for 90 minutes and are stored at 5°C ± 3°C. They must form stable suspensions in physiological saline solutions and show no evidence of auto-agglutination. A viability check must be performed on the suspensions and no growth must be evident after 10 days of incubation at 37°C ± 2°C. The packed cell volume (PCV) of the killed suspensions can be determined by centrifuging 1 ml volumes in Wintrobe tubes at 3000 ***g*** for 75 minutes.

2.3. Buffered *Brucella* antigen tests (BBAT)

2.3.1. Rose bengal test

This test is a simple spot agglutination test using antigen stained with rose bengal and buffered to a low pH, 3.65 ± 0.05 (Morgan *et al*., 1969).

2.3.1.1. Antigen production

Antigen for the RBT is prepared by depositing killed *B. abortus* S99 or S1119-3 cells by centrifugation at 23,000 ***g*** for 10 minutes (or 14,000 ***g*** for 40 minutes) at 5°C ± 3°C, and uniformly resuspending in sterile phenol saline (0.5%) at the rate of 1 g to 22.5 ml. (Note: if sodium carboxymethyl cellulose is used as the sedimenting agent during preparation of the cell concentrate, insoluble residues must be removed by filtering the suspension through an AMF-CUNO Zeta-plus prefilter [Type CPR 01A] before staining.) In case of production of cells in liquid media (e.g. in bioreactor), it is possible to concentrate the bacterial suspension (up to 40 times) before centrifugation, using a tangential flow filtration system (TFFS) with 0.1 μm cassette and doing three washes (1:3 ratio) with sterile phenol saline (0.5%). To every 35 ml of this suspension, 1 ml of 1% (w/v) rose bengal (CI No. 45440) in sterile purified water is added, and the mixture is stirred for 2 hours at room temperature. The mixture is filtered through sterile cotton wool, and centrifuged at 10,000 ***g*** to deposit the stained cells, which are then uniformly resuspended at the rate of 1 g cells to 7 ml of diluent (21.1 g of NaOH dissolved in 353 ml of sterile phenol saline, followed by 95 ml of lactic acid, and adjusted to 1056 ml with sterile phenol saline). The colour of this suspension should be an intense pink and the supernatant of a centrifuged sample should be free of stain; the pH should be 3.65 ± 0.05. After filtration through cotton wool, the suspension is filtered twice through a Sartorius No. 13430 glass fibre prefilter, adjusted to a PCV of approximately 8%, pending final standardisation against serum standardised against the WOAHISS, and stored at 5°C ± 3°C in the dark. The antigen should be stored as recommended by the manufacturer. It should not be frozen.

2.3.1.2. Antigen standardisation

When used in the standard test procedure, the RBT antigen should give a clearly positive reaction with 1/45 dilution, but not 1/55 dilution, of the WOAHISS diluted in 0.5% phenol saline or normal saline.

Additional checks may be performed with the ISaBmS. The highest dilution (in negative goat serum) of this standard that must give a positive result and the lowest dilution (in negative goat serum) that must simultaneously give a negative result have been established at 1/16 and 1/200, respectively (McGiven *et al*., 2011).

It is also be advisable to compare the reactivity of new and previously standardised batches of antigen using a panel of well-defined reference sera.

However the above standardisation against the WOAHISS is probably a cause of the reduced sensitivity of some RB antigen batches for diagnosing *B. melitensis* infection in small ruminants and of the discrepancies with the CFT (Blasco *et al*., 1994a). When testing small ruminants, the discrepancies with the CFT can be minimised by using three volumes

of serum and one volume of antigen (e.g. 75 µl and 25 µl, respectively) in place of an equal volume of each as mentioned in the standard test procedure. However, this modification of the RBT should not be recommended for testing cattle and pig sera.

2.3.1.3. Test procedure

i) Bring the serum samples and antigen to room temperature (22°C ± 4°C); only sufficient antigen for the day's tests should be removed from the refrigerator.

ii) Place 25–30 µl of each serum sample on a white tile, enamel or plastic plate, or in a WHO haemagglutination plate.

iii) Shake the antigen bottle well, but gently, and place an equal volume of antigen near each serum spot.

iv) Immediately after the last drop of antigen has been added to the plate, mix the serum and antigen thoroughly (using a clean glass or plastic rod for each test) to produce a circular or oval zone approximately 2 cm in diameter.

v) The mixture is agitated gently for 4 minutes at room temperature (22°C ± 4°C) on a rocker or three-directional agitator (if the reaction zone is oval or round, respectively).

vi) Read for agglutination immediately after the 4-minute period is completed. Any visible coloured agglutination is considered to be a positive reaction. A control serum that gives a minimum positive reaction should be tested before each day's tests are begun to verify the sensitivity of test conditions.

The RBT is very sensitive. However, like all other serological tests, it could sometimes give a positive result in cattle because of *B. abortus* S19 vaccination or FPSR. The same phenomenon occurs in small ruminants or pigs affected by FPSR and in small ruminants vaccinated with *B. melitensis* Rev.1. Therefore positive reactions should be investigated using suitable confirmatory or complementary strategies (including epidemiological investigation). Conversely, false-negative reactions occur rarely. Nevertheless RBT appears to be adequate as a screening test for detecting infected herds or to guarantee the absence of infection in brucellosis-free herds or flocks.

2.3.2. Buffered plate agglutination test

2.3.2.1. Antigen production

Antigen for the BPAT is prepared from *B. abortus* S1119-3 according to the procedure described by Angus & Barton (1984).

Two staining solutions are required: brilliant green (2 g/100 ml) and crystal violet (1 g/100 ml) both certified stains dissolved in purified water. Once prepared, the two solutions should be stored separately for a period of 24 hours, and then mixed together in equal volumes in a dark bottle and stored in a refrigerator for a period of not less than 6 months before use. The mixed stain may only be used between 6 and 12 months after initial preparation.

Buffered diluent is prepared by slowly dissolving sodium hydroxide (150 g) in 3–4 litres of sterile phenol saline. Lactic acid (675 ml) is added to this solution, and the final volume is adjusted to 6 litres by adding sterile phenol saline. The pH of the solution should be 3.65 ± 0.05.

Brucella abortus S1119-3 packed cells are diluted to a concentration of 250 g/litre in phenol saline; 6 ml of stain is added per litre of cell suspension, and the mixture is shaken thoroughly before being filtered through sterile absorbent cotton. The cells are centrifuged at 10,000 ***g*** at 5°C ± 3°C, and the packed cells are then resuspended at a concentration of 50 g/100 ml in buffered diluent (as described above). This mixture is shaken thoroughly for 2 hours, and is then further diluted by the addition of 300 ml of buffered diluent per 100 ml of suspended cells (i.e. final concentration of 50 g packed cells/400 ml buffered diluent). The mixture is stirred at room temperature for 20–24 hours before the cell concentration is adjusted to 11% (w/v) in buffered diluent. This suspension is stirred overnight before testing. Pending final

quality control tests, the antigen is stored at 5°C± 3°C until required for use. The antigen should not be frozen.

The pH of the buffered plate antigen should be 3.70 ± 0.03 and the pH of a serum–antigen mixture at a ratio of 8:3 should be 4.02 ± 0.04. The 11% stained-cell suspension should appear blue–green. Each batch of buffered plate antigen should be checked by testing at least 10 weakly reactive sera and comparing the results with one or more previous batches of antigen. If possible, the antigen batches should be compared with the standard antigen prepared by the NVSL, USDA (see footnote 4 for address). There is, however, no international standardisation procedure established for use with either the WOAHISS or with the ISaBmS.

2.3.2.2. Test procedure

i) Bring the serum samples and antigen to room temperature (22°C ± 4°C); only sufficient antigen for the day's tests should be removed from the refrigerator.

ii) Shake the sample well. Place 80 µl of each serum sample on a glass plate marked in 4 × 4 cm squares

iii) Shake the antigen bottle well, but gently, and place 30 µl of antigen near each serum spot.

iv) Immediately after the last drop of antigen has been added to the plate, mix the serum and antigen.

v) Thoroughly (using a clean glass or plastic rod for each test) to produce a circular zone approximately 3 cm in diameter.

vi) After the initial mixing, the plate should be rotated three times in a tilting motion to ensure even dispersion of the reagents, and then incubated for 4 minutes in a humid chamber at ambient temperature.

vii) The plate should be removed and rotated as above, and then returned for a second 4-minute incubation.

viii) Read for agglutination immediately after the 8-minute period is completed. Any visible reaction is considered to be positive. A control serum that gives a minimum positive reaction should be tested before each day's tests are begun to verify the sensitivity of test conditions.

Like the RBT, the test is very sensitive in cattle, especially for detection of vaccine-induced antibody, and positive samples should be retested using a confirmatory or complementary test(s). False-negative reactions may occur, usually due to prozoning, which may be overcome by diluting the serum or retesting after a given time. While the BPAT has been extensively used with apparent good results in small ruminants and pigs in some countries, its diagnostic value in these species has not been reported at international level.

2.4. Complement fixation test

The CFT is widely used but it is complex to perform, and requires good laboratory facilities and adequately trained staff to accurately titrate and maintain the reagents. There are numerous variations of the CFT in use, but this test is most conveniently carried out in a microtitre format. Warm or cold fixation may be used for the incubation of serum, antigen and complement: either 37°C ± 2°C for 30 minutes or 5°C ± 3°C for 14–18 hours. A number of factors affect the choice of the method: anti-complementary activity in serum samples of poor quality is more evident with cold fixation, while fixation at 37°C ± 2°C increases the frequency and intensity of prozones, and a number of dilutions must be tested for each sample.

Several methods have been proposed for the CFT using different concentrations of fresh or preserved sheep red blood cells (SRBCs) (a 2%, 2.5% or 3% suspension is usually recommended) sensitised with an equal volume of rabbit anti-SRBC serum diluted to contain several times (usually from two to five times) the minimum concentration required to produce 100% lysis of SRBCs in the presence of a titrated solution of guinea-pig complement. The latter is independently titrated (in the presence or absence of antigen according to the method) to determine the amount of complement required to produce either 50% or 100% lysis of sensitised SRBCs in a unit volume of a standardised suspension; these are defined

as the 50% or 100% haemolytic unit of complement/minimum haemolytic dose (C'H or MHD_{50} or C'H or MHD_{100}), respectively. It is generally recommended to titrate the complement before each set of tests, a macromethod being preferred for an optimal determination of $C'H_{50}$. Usually, 1.25–2 $C'H_{100}$ or 5–6 $C'H_{50}$ are used in the test.

Barbital (veronal) buffered saline is the standard diluent for the CFT. This is prepared from tablets available commercially; otherwise it may be prepared from a stock solution of sodium chloride (42.5 g), barbituric acid (2.875 g), sodium diethyl barbiturate (1.875 g), magnesium sulphate (1.018 g), and calcium chloride (0.147 g) in 1 litre of purified water, diluted by the addition of four volumes of 0.04% gelatine solution before use. However, this buffer contains barbituric derivatives that are no longer available in several countries. Satisfactory results may be also obtained with a barbituric-free solution of sodium chloride 0.85% containing calcium and magnesium, prepared by adding 1 ml of a stock solution of 1 M magnesium chloride and 0.3 M calcium chloride (anhydrous $MgCl_2$: 9.5 g $CaCl_2$: 3.7 g; purified water: up to 100 ml) (stored in small amounts at 5°C ± 3°C) to 1 litre of saline solution (Alton *et al*., 1988). The pH is critical and must be strictly adjusted to 7.35 (± 0.05). The replacement of the veronal buffer by this barbituric-free buffer has been validated in the WOAH Brucellosis Reference Laboratory in France.

2.4.1. Antigen production

Numerous variations of the test exist but, whichever procedure is selected, the test must use an antigen that has been prepared from an approved smooth strain of *B. abortus*, such as S99 or S1119-3, and standardised against the WOAHISS. Antigen for the CFT can be prepared following specialised procedures (Alton *et al*., 1988) or a whole cell antigen can be used after diluting the stock suspension such that the PCV of the concentrated antigen suspension for CFT is approximately 2% before standardisation against the WOAHISS.

2.4.2. Antigen standardisation

The antigen should be standardised to give 50% fixation at a dilution of 1/200 of the WOAHISS and must also show complete fixation at the lower serum dilutions, because too weak (or too strong) a concentration of antigen may not produce 100% fixation at the lower dilutions of serum. When two dilutions of antigen are suitable, the more concentrated antigen suspension must be chosen in order to avoid prozone occurrence. The appearance of the antigen, when diluted 1/10 must be that of a uniform, dense, white suspension with no visible aggregation or deposit after incubation at 37°C ± 2°C for 18 hours. It must not produce anti-complementary effects at the working strength for the test. The antigen is stored at 5°C ± 3°C and should not be frozen.

2.4.3. Test procedure (example)

The undiluted test sera and appropriate working standards should be inactivated for 30 minutes in a water bath at 60°C ± 2°C. If previously diluted with an equal volume of veronal buffered saline, these sera could be inactivated at 58°C ± 2°C for 50 minutes. Usually, only one serum dilution is tested routinely (generally 1/4 or 1/5 depending on the CF procedure chosen), but serial dilutions are recommended for trade purposes and when clinical signs have been reported in order to detect prozone.

Using standard 96-well microtitre plates with round (U) bottoms, the technique is usually performed as follows:

i) Volumes of 25 µl of diluted inactivated test serum are placed in the well of the first, second and third rows. The first row is an anti-complementary control for each serum. Volumes of 25 µl of CFT buffer are added to the wells of the first row (anti-complementary controls) to compensate for lack of antigen. Volumes of 25 µl of CFT buffer are added to all other wells except those of the second row. Serial doubling dilutions are then made by transferring 25 µl volumes of serum from the third row onwards; 25 µl of the resulting mixture in the last row are discarded.

ii) Volumes of 25 µl of antigen, diluted to working strength, are added to each well except in the first row.

iii) Volumes of 25 µl of complement, diluted to the number of units required, are added to each well.

iv) Control wells containing:

a) diluent only,

b) complement + diluent,

c) antigen + complement + diluent,

are set up to contain 75 µl total volume in each case.

A control serum that gives a minimum positive reaction should be tested in each set of tests to verify the sensitivity of test conditions.

v) The plates are incubated at 37°C ± 2°C for 30 minutes or at 5°C ± 3°C overnight, and a volume (25 or 50 µl according to the technique) of sensitised SRBCs is added to each well. The plates are re-incubated at 37°C ± 2°C for 30 minutes.

vi) The results are read after the plates have been centrifuged at 1000 ***g*** for 10 minutes at 5°C ± 3°C or left to stand at 5°C ± 3°C for 2–3 hours to allow unlysed cells to settle. The degree of haemolysis is compared with standards corresponding to 0, 25, 50, 75 and 100% lysis. The absence of anti-complementary activity is checked for each serum in the first row.

vii) Standardisation of results of the CFT

A unit system that is based on the WOAHISS exists for the standardisation of results. This serum contains 1000 ICFTU per ml. If this serum is tested in a given method and gives a titre of, for example 200 (50% haemolysis), then the factor for an unknown serum tested by that method can be found from the formula: 1000 × 1/200 × titre of test serum = number of ICFTU of antibody in the test serum per ml. The WOAHISS contains specific IgG; national standard sera should also depend on this isotype for their specific complement-fixing activity. Difficulties in standardisation arise because different techniques selectively favour CF by different immunoglobulin isotypes. It is recommended that any country using the CFT on a national scale should obtain agreement among the different laboratories performing the test to use the same method in order to obtain the same level of sensitivity. To facilitate comparison between countries, results should always be expressed in ICFTUs, calculated in relation to those obtained in a parallel titration with a standard serum, which in turn may be standardised against the WOAHISS.

viii) Interpretation of the results: Sera giving a titre equivalent to 20 ICFTU/ml or more are considered to be positive.

Animals that have been vaccinated with *B. abortus* S19 or *B. melitensis* Rev.1 between 3 and 6 months are usually considered to be infected if the sera give positive fixation at a titre of 30 or greater ICFTU/ml when the animals are tested at an age of 18 months or older.

This procedure is an example, other volumes and quantities of reagents could be chosen provided that the test is standardised against the WOAHISS as described above and the results expressed in ICFTU/ml.

The CFT is usually very specific but less sensitive than RBT and ELISA, particularly in the case of swine, as swine complement interacts with guinea-pig complement to produce a pro-complementary activity that reduces the sensitivity. Thus, the CFT has a reduced sensitivity for diagnosing *B. suis* infection, is not capable of eliminating the FPSR problem, and can be recommended only as a complementary test in swine. Moreover, like most serological tests, the CFT can be positive in ruminants after *B. abortus* S19 or *B. melitensis* Rev.1 vaccination and it is not specific enough in presence of FPSR. Therefore, CFT results should be investigated using suitable confirmatory or complementary strategies.

2.5. Enzyme-linked immunosorbent assays

2.5.1. Indirect ELISA

Numerous variations of the I-ELISA have been described for cattle, small ruminants, camelids and pigs employing different antigen preparations, antiglobulin-enzyme conjugates, and substrate/

chromogens. *Brucella abortus* strain 99 (Weybridge) (S99)[3] or *B. abortus* strain 1119-3 (USDA) (S1119-3)[4] should be used for production of these antigens, but *B. melitensis* strain 16M can also be suitable for such a purpose. Several commercial I-ELISAs using whole cell, S-LPS or the OPS as antigens that have been validated in extensive field trials are available and are in wide use. Nevertheless, the technique used and the interpretation of results must have been validated in accordance with the principles laid down in Chapter 1.1.6 *Validation of diagnostic assays for infectious diseases of terrestrial animals*. The OPS antibody epitopes from these strains have also been exactly replicated through chemical synthesis and successfully used as antigens in ELISA, but these assays await full validation.

2.5.1.1. Test standardisation of the I-ELISA (EU, 2008; McGiven *et al.*, 2011)

2.5.1.1.1. Infection with *Brucella* in cattle

i) A 1/2 pre-dilution of the WOAHELISA$_{WP}$SS or a 1/16 pre-dilution of the WOAHELISA$_{SP}$SS made up in a negative bovine serum (or in a negative pool of bovine sera) must give a positive reaction;

and

ii) A 1/8 pre-dilution of the WOAHELISA$_{WP}$SS or a 1/64 pre-dilution of the WOAHELISA$_{SP}$SS made up in a negative bovine serum (or in a negative pool of bovine sera) must give a negative reaction;

and

iii) The WOAHELISA$_{N}$SS must always give a negative reaction.

2.5.1.1.2. Infection with *Brucella* in sheep and goats:

i) A 1/64 pre-dilution of the lSaBmS made up in a negative goat serum (or in a negative pool of goat sera) must give a positive reaction;

and

i) A 1/750 pre-dilution of the lSaBmS made up in a negative goat serum (or in a negative pool of goat sera) must give a negative reaction;

and

i) The above-mentioned negative goat serum (or negative pool of goat sera) must always give a negative reaction.

2.5.1.1.3. Infection with *Brucella* in pigs and camelids:

i) In the absence of appropriate international standard sera the test should be duly validated and the cut-off established in the test population with appropriate validation techniques (see chapter 1.1.6).

The I-ELISAs that use S-LPS or OPS as antigens are highly sensitive for the detection of anti-*Brucella* antibodies in cattle, small ruminants and pigs, but are not capable of fully resolving the problem of differentiating between antibodies resulting from *B. abortus* S19 and *B. melitensis* Rev.1 vaccination. The *B. abortus* RB51 vaccine may also interfere in S-LPS-based I-ELISAs.

Positive reactions should be investigated using suitable confirmatory or complementary strategies as for BBAT and CFT.

Using I-ELISA standardised against WOAH standard sera described above, the diagnostic sensitivity should be equal to or greater than that of the BBATs (RBT/BPAT) or the CFT in the testing of infected cattle, small ruminants and pigs. However, the specificity would usually be lower (EFSA, 2006; 2009; Greiner *et al.,* 2009; Gusi *et al.,* 2019).

The problem of FPSR may be reduced but not fully resolved, in pigs in particular, by performing I-ELISAs using extracts from rough strains of *Brucella*. Most FPSR are a result of cross reaction with the OPS portion of the S-LPS molecule; cross-reaction among core epitopes is less frequent but does exist. The use of chaotropic I-ELISAs or procedures using heterologous extracts or

Brucella cytosolic proteins as antigens does not resolve this problem, at least in cattle (Munoz *et al*., 2005). Moreover, in the context of FPSR, the most specific diagnostic procedure remains the brucellin skin test (see Section B.3.1 below).

Monoclonal, polyclonal antiglobulin or protein G or AG enzyme conjugates may be used depending on availability and performance requirements. A monoclonal antibody (MAb) specific for the heavy chain of bovine IgG_1 may provide some improvement in specificity at the possible cost of some loss of sensitivity while a protein G or AG enzyme conjugate may provide a reagent useful for testing a variety of mammalian species.

Several commercial I-ELISAs are available. Some protocols are less sensitive or less specific than others; therefore results obtained from different assays are not always comparable. I-ELISA for diagnosing anti-*Brucella* antibodies in small ruminants and pigs is essentially the same as that described for cattle, but the cut-off should have been properly established for these species using the appropriate validation techniques (see chapter 1.1.6), and, moreover, I-ELISA for sheep and goats should be standardised against the lSaBmS (McGiven *et al*., 2011).

Whatever the I-ELISA format used:

i) A positive and a negative control are included in each plate. OD (optical density) ranges to be obtained with these two controls must be established to define the criteria for validating each plate results. The OD of the positive control is the one with which the OD of each test serum is compared to establish the final result (negative or positive).

ii) An additional positive serum (internal control) must be included in each plate to validate the repeatability of the test from plate to plate and from day to day.

2.5.2. Competitive ELISA

Several variations of the C-ELISA, using S-LPS or OPS as antigens, have been described for cattle, small ruminants, camelids and pigs employing different antiglobulin-enzyme conjugates, substrate or chromogens and antigens prepared from different smooth *Brucella* strains. Nevertheless, the technique used and the interpretation of results must have been validated in accordance with the principles laid down in chapter 1.1.6.

2.5.2.1. Test standardisation of the C-ELISA (EU, 2008; McGiven *et al.*, 2011)

2.5.2.1.1. Infection with *Brucella* in cattle:

i) A 1/2 pre-dilution of the $ELISA_{WP}SS$ or a 1/16 pre-dilution of the $WOAHELISA_{SP}SS$ made up in a negative bovine serum (or in a negative pool of bovine sera) must give a positive reaction;

and

ii) A 1/8 pre-dilution of the $WOAHELISA_{WP}SS$ or a 1/64 pre-dilution of the $WOAHELISA_{SP}SS$ made up in a negative bovine serum (or in a negative pool of bovine sera) must give a negative reaction;

and

iii) The $WOAHELISA_{N}SS$ must always give a negative reaction.

2.5.2.1.2. Infection with *Brucella* in sheep and goats:

i) A 1/8 pre-dilution of the lSaBmS made up in a negative goat serum (or in a negative pool of goat sera) must give a positive reaction;

and

ii) a 1/300 pre-dilution of the lSaBmS made up in a negative goat serum (or in a negative pool of goat sera) must give a negative reaction;

and

iii) the above-mentioned negative goat serum (or negative pool of goat sera) must always give a negative reaction.

2.5.2.1.3. Infection with *Brucella* in pigs:

i) In the absence of an international standard serum for porcine brucellosis, the test should be duly validated and the cut-off established in the test population with appropriate validation techniques (see chapter 1.1.6).

Several commercial C-ELISAs are available. Some protocols are less sensitive or less specific than others, therefore results obtained from different assays are not always comparable. The cut-off should have been properly established using the appropriate validation techniques (see chapter 1.1.6).

The C-ELISA using an MAb specific for one of the epitopes of the *Brucella* sp. OPS has been shown in cattle, sheep and swine to have usually, but not always, higher specificity but lower sensitivity than the BBAT or I-ELISA (Munoz *et al*., 2005; 2012; Nielsen *et al*., 1995; Praud *et al*., 2012; Stack *et al*., 1999).

The C-ELISA may reduce but not fully eliminate the reactions caused by antibodies produced in response to vaccination. It is highly probable that the improved specificity is due to a reduction in sensitivity of the C-ELISA compared with BBAT and I-ELISA. Therefore, the results from C-ELISA reactions should not be considered in isolation but alongside suitable confirmatory or complementary strategies as for RBT, BBAT, CFT and I-ELISA.

The choice of MAb and its more or less high and unique specificity and affinity will have a distinct influence on the diagnostic performance characteristics of the assay. As with any MAb-based assays, the universal availability of the MAb or the hybridoma must also be considered with respect to international acceptance and widespread use.

Whatever the C-ELISA format used:

i) A positive and a negative control are included in each plate. OD ranges to be obtained with these two controls must be established to define the criteria for validating each plate results. The OD of the positive control is the one with which the OD of each test serum is compared to establish the final result (negative or positive).

ii) An additional positive serum (internal control) must be included in each plate to validate the repeatability of the test from plate to plate and from day to day.

2.6. Fluorescence polarisation assay

The FPA is a simple technique for measuring antigen/antibody interaction. It is a homogeneous assay in which analytes are not separated and it is therefore very rapid. However, unlike another homogeneous method (e.g. RBT) a blank/background read is required for each sample before adding the antigen. Thus it is a two-step assay.

For the diagnosis of brucellosis, a small molecular weight fragment (average 22 kD) of the OPS of *B. abortus* strain *B. abortus* 1119-3 S-LPS is labelled with fluorescein isothiocyanate (FITC) and used as the antigen. Once the blank/background read is performed (2–3 minutes), this antigen is added to diluted serum and a measure of the antibody content is obtained in about 2 minutes after the addition of antigen using a fluorescence polarisation analyser (FPM) (Nielsen *et al*., 1996).

2.6.1. Antigen production (example)

OPS from 5 g dry weight (or 50 g wet weight) of *B. abortus* S1119-3 is prepared by adding 400 ml of 2% (v/v) acetic acid, autoclaving the suspension for 15 minutes at 121°C and removing the cellular debris by centrifugation at 10,000 ***g*** for 10 minutes at 5°C ± 3°C. The supernatant solution is then treated with 20 g of trichloroacetic acid to precipitate any proteins and nucleic acids. The precipitate is again removed by centrifugation at 10,000 ***g*** for 10 minutes at 5°C ± 3°C. The supernatant fluid is dialysed against at least 100 volumes of purified water and freeze dried; 3 mg of OPS are dissolved in 0.6 ml of 0.1 M sodium hydroxide (4 g NaOH/litre) and incubated at 37°C ± 2°C for 1 hour, followed by the addition of 0.3 ml of FITC isomer 1 at a concentration of 100 mg/ml in dimethyl sulphoxide and a further incubation at 37°C ± 2°C for 1 hours. The conjugated OPS is applied to a 1 × 10 cm column packed with DEAE (diethylaminoethyl) Sephadex A 25 equilibrated

in 0.01 M phosphate buffer, pH 7.4 ± 0.2. The first fraction (after 10–15 ml of buffer) is bright green, after which the buffer is switched to 0.1 M phosphate, pH 7.4 ± 0.2. This results in the elution of 10–15 ml of buffer followed by 25–40 ml of green fluorescent material. The latter material is the antigen used in the FPA. Antigen preparation may be scaled up proportionally.

The amount of antigen used per test is determined by diluting the material derived above until a total fluorescence intensity of 250,000–300,000 is achieved using the FPM.

The antigen can be stored as a liquid for several years at 5°C ± 3°C in a dark bottle or it may be freeze-dried in dark bottles. Labelled antigen may be obtained from a limited number of commercial sources.

2.6.2. Test standardisation of the FPA (EU, 2008; McGiven *et al.*, 2011)

2.6.2.1. Infection with *Brucella* in cattle

i) the WOAHELISA$_{WP}$SS and WOAHELISA$_{SP}$SS consistently give a positive reaction;

and

ii) a 1/8 pre-dilution of the WOAHELISA$_{WP}$SS or a 1/64 pre-dilution of the WOAHELISA$_{SP}$SS made up in a negative bovine serum (or in a negative pool of bovine sera) must give a negative reaction;

and

iii) the WOAHELISA$_{N}$SS must always give a negative reaction.

2.6.2.2. Infection with smooth *Brucella* in sheep and goats

i) a 1/16 pre-dilution of the ISaBmS made up in a negative goat serum (or in a negative pool of goat sera) must give a positive reaction;

and

ii) a 1/200 pre-dilution of the ISaBmS made up in a negative goat serum (or in a negative pool of goat sera) must give a negative reaction;

and

iii) the above-mentioned negative goat serum (or negative pool of goat sera) must always give a negative reaction.

2.6.2.3. Infection with *Brucella* in pigs

i) In the absence of international standard serum for porcine brucellosis the test should be duly validated and the cut-off established in the test population with appropriate validation techniques (see chapter 1.1.6).

The diagnostic sensitivity and specificity of the FPA for bovine brucellosis are almost identical to those of the C-ELISA. The FPA for diagnosing anti-*Brucella* antibodies in small ruminants and swine is essentially the same as that described for cattle, but the cut-off should have been properly established for these species using the appropriate validation techniques (see chapter 1.1.6), and the test should be standardised against the corresponding international Standards, as mentioned above.

The FPA is capable of reducing but not fully eliminating the reactions due to residual antibody produced in response to vaccination (Nielsen *et al*., 1996). Moreover, the specificity of FPA in FPSR conditions is currently unknown in cattle and small ruminants, but it has been clearly shown that it does not resolve the FPSR problem in swine (Praud *et al*., 2012).

Accordingly, like all other serological tests, positive reactions should be investigated using suitable confirmatory and/or complementary strategies.

2.6.3. Test procedure (Nielsen *et al.*, 1996)

The FPA can be performed in glass tubes or a 96-well plate format.

Bovine sera are diluted 1/10 for the plate test or 1/100 for the tube test.

Sheep and goat as well as porcine sera are diluted 1/10 for the plate test or 1/25 (goat and porcine) and 1/40 (sheep) for the tube test.

The diluent used is 0.01 M Tris (1.21 g), containing 0.15 M sodium chloride (8.5 g), 0.05% Igepal CA630 (500 µl) (formerly NP40), 10 mM EDTA (3.73 g) per litre of purified water, pH 7.2 ± 0.2 (Tris buffer).

An initial reading to assess light scatter is obtained with the FPM after mixing. Suitably labelled titrated antigen is added, mixed and a second reading is obtained in the FPM about 2 minutes later.

A reading (in millipolarisation units, mP) over the established threshold level is indicative of a positive reaction.

A typical threshold level is 90–100 mP units, however, the test should be standardised locally against the corresponding WOAH reference standard sera (as mentioned above). A strong positive, a weak positive and a negative working standard serum (standardised against the above-mentioned WOAH reference standard sera) should be included.

2.6.3.1. Example for bovine sera

i) 1 ml of diluent is added to a 10 × 75 mm borosilicate glass tube followed by 10 µl of serum or 20 µl of EDTA-treated blood. For the 96-well format, 20 µl of serum is added to 180 µl of buffer. It is important to mix well. A reading is obtained on the FPM to determine light scatter.

ii) A volume of antigen, which results in a total fluorescence intensity of 250–300 × 10^3, is added to the tube and mixed well. This volume will vary from batch to batch, but is generally in the range of about 10 µl. A second reading is obtained on the FPM after incubation at room temperature (22°C ± 4°C) for approximately 2 minutes for serum and 15 seconds for EDTA-treated blood.

iii) A reading above the predetermined threshold is indicative of a positive reaction.

2.7. Serum agglutination test (cattle only)

The SAT has been used with success for many years in surveillance and control programmes for bovine brucellosis, particularly in northern Europe. Its specificity is significantly improved with the addition of EDTA to the antigen (MacMillan & Cockrem, 1985).

The antigen represents a bacterial suspension of *B. abortus* strain 99 or *B. abortus* strain 1119-3 in phenol saline (NaCl 0.85% [w/v] and phenol at 0.5% [v/v]). Formaldehyde must not be used. Antigens may be delivered in the concentrated state provided the dilution factor to be used is indicated on the bottle label. EDTA may be added to the antigen suspension to 5 mM final test dilution to reduce the level of false-positive results. Subsequently the pH of 7.2 ± 0.2 must be readjusted in the antigen suspension.

The WOAHISS contains 1000 IUs of agglutination. The antigen should be prepared without reference to the cell concentration, but its sensitivity must be standardised in relation to the WOAHISS in such a way that the antigen produces either 50% agglutination with a final serum dilution of 1/600 to 1/1000 or 75% agglutination with a final serum dilution of 1/500 to 1/750. It may also be advisable to compare the reactivity of new and previously standardised batches of antigen using a panel of defined sera.

The test is performed either in tubes or in microplates. The mixture of antigen and serum dilutions should be incubated for 16–24 hours at 37°C ± 2°C. If the test is carried out in microplates, the incubation time can be shortened to 6 hours. At least three dilutions must be prepared for each serum in order to refute prozone negative responders. Dilutions of suspect serum must be made in such a way that the reading of the reaction at the positivity limit is made in the median tube (or well for the microplate method).

Interpretation of results: The degree of *Brucella* agglutination in a serum must be expressed in IU per ml. A serum containing 30 or more IU per ml is considered to be positive.

2.8. Native hapten and cytosol protein-based tests (ruminants only)

In cattle, native hapten tests[5] are highly specific in *B. abortus* S19 vaccination contexts, and have been used successfully in combination with the RBT as a screening test. The optimal sensitivity (close to that of CFT but significantly lower than that of RBT and S-LPS based I-ELISAs) is obtained in a reverse radial immunodiffusion (RID) system in which the serum diffuses into a hypertonic gel containing the polysaccharide, but the double gel diffusion assay is also useful (Munoz *et al*., 2005). Calves vaccinated subcutaneously with the standard dose of *B. abortus* S19 at 3-5 months of age are negative usually by 2 months after vaccination, and adult cattle vaccinated subcutaneously 4–5 months previously with the reduced dose of *B. abortus* S19 do not give positive reactions unless the animals become infected and shed the vaccine strain in their milk. The conjunctival vaccination (both in young and adults) reduces significantly the time to obtain a negative response in native hapten tests. A characteristic of the native hapten tests is that a positive result correlates with *Brucella* shedding as shown in experimentally and in naturally infected cattle (Jones *et al*., 1980). In case of FPSR caused by *Yersinia enterocolitica* O:9 and FPSR of unknown origin in cattle, gel precipitation tests using native hapten or *Brucella* cytosol proteins usually give negative results (Munoz *et al*., 2005).

These native hapten tests are also of interest in sheep and goats as they are very specific for discriminating the serological responses of infected animals (positive) from those induced in *B. melitensis* Rev.1 vaccinated animals (usually negative after a given time post-vaccination). The optimal diagnostic sensitivity (around 90%) is obtained in the double gel diffusion or RID tests for sheep and goats, respectively.

2.9. Milk tests

An efficient means of screening dairy herds is by testing milk from the bulk tank. When a positive test result is obtained, all cows contributing milk should be blood tested. The milk I-ELISA is a sensitive and specific test, and is particularly valuable for testing large herds. The MRT is a suitable alternative if the milk I-ELISA is not available. However, the MRT is not suitable in milk from small ruminants.

2.9.1. Milk I-ELISA (cattle and sheep and goats only)

As with the serum I-ELISA, many variations of the milk I-ELISA are possible. Several commercial I-ELISAs are available that have been validated in extensive field trials and are in wide use. In the interests of international harmonisation, the three WOAH ELISA Standard Sera should be used by national reference laboratories to check or standardise a particular test for use in cattle.

2.9.1.1. Test standardisation of the Milk I-ELISA in dairy cattle

The milk I-ELISA for cattle should be standardised such that the WOAH ELISA strong positive standard when diluted 1/125 in negative serum and further diluted 1/10 in negative milk consistently tests positive (EU, 2008).

Bulk milk samples are generally tested at much lower dilutions than sera, i.e. undiluted to 1/2 to 1/10 in diluent buffer, with the remainder of the assay being similar to that described for serum.

FPSR may be observed in milk I-ELISA, but usually less frequently than with blood tests.

The I-ELISA for diagnosing anti-*Brucella* antibodies in sheep or goat milk is essentially the same as that described for cattle, but the cut-off should be properly established for these species using the appropriate validation techniques (see chapter 1.1.6). However there are no international standardisation recommendations of the milk I-ELISA against the corresponding ISaBmS.

5 The detailed procedure can be obtained from the Brucellosis Laboratory, Centro de Investigación y Tecnología Agroalimentaria / Gobierno de Aragón, Avenida Montañana 930, 50059 Zaragoza, Spain.

2.9.2. Milk ring test (cattle only)

In lactating cattle, the MRT can be used for screening herds for brucellosis.

In large herds (> 100 lactating cows), the sensitivity of the test becomes less reliable. The MRT may be adjusted to compensate for the dilution factor from bulk milk samples from large herds. The samples are adjusted according to the following formula: herd size < 150 animals use, 1 ml bulk milk; 150–450 animals, use 2 ml milk sample, 451–700 animals, use 3 ml milk sample.

False-positive reactions may occur in cattle vaccinated less than 4 months prior to testing, in samples containing abnormal milk (such as colostrum) or in cases of mastitis. Therefore, it is not recommended to use this test in very small farms where these problems have a greater impact on the test results.

2.9.2.1. Antigen production

MRT antigen is prepared from concentrated, killed *B. abortus* S99 or S1119-3 cell suspension, grown as described previously. It is centrifuged at, for example, 23,000 ***g*** for 10 minutes at 5°C ± 3°C, followed by resuspension in haematoxylin-staining solution. Various satisfactory methods are in use; one example is as follows: 100 ml of 4% (w/v) haematoxylin (CI No. 75290) dissolved in 95% ethanol is added to a solution of ammonium aluminium sulphate (5 g) in 100 ml of purified water and 48 ml of glycerol; 2 ml of freshly prepared 10% (w/v) sodium iodate is added to the solution. After standing for 30 minutes at room temperature (22°C ± 4°C), the deep purple solution is added to 940 ml of 10% (w/v) ammonium aluminium sulphate in purified water. The pH of this mixture is adjusted to 3.1 ± 0.2, and the solution must be aged by storage at room temperature in the dark for 45–90 days.

Before use, the staining solution is shaken and filtered through cotton wool. The packed cells are suspended in the staining solution at the rate of 1 g per 30 ml stain, and held at room temperature (22°C ± 4°C) for 48 hours (some laboratories prefer to heat at 80°C for 10 minutes instead). The stained cells are then deposited by centrifugation, and washed three times in a solution of sodium chloride (6.4 g), 85% lactic acid (1.5 ml) and 10% sodium hydroxide (4.4 ml) in 1.6 litres of purified water, final pH 3.0 ± 0.2. The washed cells are resuspended at the rate of 1 g in 27 ml of a diluent consisting of 0.5% phenol saline, adjusted to pH 4.0 ± 0.2 by the addition of 0.1 M citric acid (approximately 2.5 ml) and 0.5 M disodium hydrogen phosphate (approximately 1 ml) and maintained at 5°C± 3°C for 24 hours. The mixture is filtered through cotton wool, the pH is checked, and the PCV is determined and adjusted to approximately 4%.

2.9.2.2. Antigen standardisation

The antigen should be standardised against the WOAHISS so that a 1/500 dilution is positive and 1/1000 dilution is negative. The sensitivity of the new batch should be compared as well with a previously standardised batch using a panel of samples of varying degrees of reaction prepared by diluting a positive serum in milk.

The antigen should be stored as recommended by the manufacturer but usually at 5°C ± 3°C.

The pH of the antigen should be 3.5 (± 0.2) and its colour should be dark blue. A little free stain in the supernatant of a centrifuged sample is permissible. When diluted in milk from a brucellosis-free animal, the antigen must produce a uniform coloration of the milk layer with no deposit and no coloration of the cream layer.

2.9.2.3. Test procedure

The test is performed on bulk tank milk samples. If necessary, samples could be pre-treated with preservative (0.1% formalin or 0.02% bronopol) for 2–3 days at 5°C ± 3°C prior to use.

i) Bring the milk samples and antigen to room temperature (22°C ± 4°C); only sufficient antigen for the day's tests should be removed from the refrigerator.

ii) Gently shake the antigen bottle well.

iii) The test is performed by adding 30–50 µl of antigen to a 1–2 ml volume of whole milk (the volume of milk may be increased for bulk samples from larger herds – see above).

iv) The height of the milk column in the tube must be 20–25 mm. The milk samples must not have been frozen, heated, subjected to violent shaking or stored for more than 72 hours.

v) The milk/antigen mixtures are normally incubated at 37°C ± 2°C for 1 hour, together with positive and negative working standards. However, overnight incubation at 5°C± 3°C increases the sensitivity of the test and allows for easier reading.

vi) A strongly positive reaction is indicated by formation of a dark blue ring above a white milk column. Any blue layer at the interface of milk and cream should be considered to be positive as it might be significant, especially in large herds.

vii) The test is considered to be negative if the colour of the underlying milk exceeds that of the cream layer.

viii) When the MRT is adjusted for large herd sizes (2 or 3 ml of milk used), 0.1 ml of pooled negative cream is added to the test tube and is followed by 30–50 µl of the ring test antigen. After mixing, the test is incubated and read in the same manner as the unadjusted MRT. The negative pooled cream is collected from the separation of composite, unpasteurised milk from a brucellosis negative herd of 25 or more cows.

2.10. Serological tests in wildlife

Serological investigations in wild species are usually carried out for screening purposes. In these particular circumstances, adequate specificity is of paramount importance. The RBT can be recommended as a general purpose diagnostic test in all wildlife species. The CFT could also be recommended for such purpose, but the selection of the complement inactivation temperature and the cut-off titres have not been properly documented in all wildlife species. Both tests require the use of high quality serum samples that are not easy to obtain in wildlife studies. When poor quality serum samples are tested in both RBT and CFT, the results are frequently uninterpretable. The I- and C-ELISAs appear to be useful for epidemiological sero-surveys in wild animals as both are generally more reliable than both RBT and CFT, and, moreover, can be used with poor quality and haemolysed sera (Stack *et al*., 1999). Another advantage of the ELISAs is that if serum is not available, it is possible to test meat juice samples. Attention must be paid to the conjugate used in the I-ELISA as it must have a satisfactory affinity for the corresponding antibody isotypes of the wild species under study. However, in wild species, the interpretation of ELISA results may be problematic, due to the lack of validation studies. Whenever possible, the cut-off of ELISAs should be properly established for the particular species using the appropriate validation techniques (see chapter 1.1.6). Nevertheless, where positive or doubtful serological results are found, a bacteriological investigation should be conducted, when possible, to clarify the diagnosis.

3. Tests for cellular immunity

3.1. Brucellin skin test

An alternative immunological assay is the brucellin skin test, which can be used for screening unvaccinated herds, provided that a purified (free of S-LPS) and standardised antigen preparation is used. The brucellin skin test has a very high specificity, such that serologically negative unvaccinated cattle that are positive reactors to the brucellin test should be regarded as infected animals (Pouillot *et al*., 1997). The brucellin skin test also has a high sensitivity for the diagnosis of *B. melitensis* infection in small ruminants and, in the absence of vaccination, is considered one of the most specific diagnostic tests.

Brucellin was developed for use in ruminants, but is also effective for confirming the disease at the herd level in pigs. Field trials have also shown its good sensitivity in *Brucella*-infected pigs (Dieste-Perez *et al*., 2014). Also, results of this test may aid the interpretation of serological reactions thought to be FPSR due to infection with cross-reacting bacteria, as FPSR affected animals always give negative results in the skin test (Dieste-Perez *et al*., 2014; Pouillot *et al*., 1997). Preliminary studies have suggested that brucellin can be used as a confirmatory diagnostic test in camels (Khalafalla *et al.,* 2020).

Animals vaccinated with *B. melitensis* Rev.1, *B. abortus* S19 or RB51 can give positive results in this test for years (Pouillot *et al*., 1997; De Massis *et al.*, 2005; 2015). Therefore this test cannot be recommended either as the sole diagnostic test or for the purposes of international trade in areas where *Brucella* vaccines are used. Moreover, not all infected animals react, therefore this test alone cannot be recommended as an individual diagnostic test or for the purposes of international trade. However, due to its high specificity and its adequate sensitivity at the herd or flock level, it can be recommended for herd/flock surveillance in brucellosis-free areas.

It is essential to use a standardised, defined brucellin preparation that does not contain S-LPS antigen, as this may provoke nonspecific inflammatory reactions or interfere with subsequent serological tests.

Although the brucellin test is probably the most specific indirect assay for diagnosing brucellosis (in unvaccinated animals), the final diagnosis should not be made solely on the basis of positive intradermal reactions given by a few animals in the herd, and should be supported by a complementary diagnostic test. The intradermal inoculation of brucellin induces a temporary anergy in the cellular immune response, at least in some animal species (Blasco *et al*., 1994b). Therefore an interval of 6 weeks is generally recommended between two tests on the same animal.

3.1.1. Test procedure

3.1.1.1. Infection with *Brucella* in cattle

i) A volume of 0.1 ml of brucellin (2000 Units/ml) is injected intra-dermally into the caudal fold, the skin of the flank, or the side of the neck.

ii) The test is read after 48–72 hours.

iii) The skin thickness at the injection site is measured with vernier callipers before injection and at re-examination.

iv) A strong positive reaction is easily recognised by local swelling and induration. However, borderline reactions require careful interpretation. Skin thickening of 1.5–2 mm would be considered as a positive reaction.

3.1.1.2. Infection with *Brucella* in sheep and goats

i) A volume of 0.1 ml of brucellin (2000 Units/ml) is injected intra-dermally into the lower eyelid.

ii) The test is read after 48 hours.

iii) Any visible or palpable reaction of hypersensitivity, such as an oedematous reaction leading to an elevation of the skin or thickening of the eyelid (≥ 2 mm), should be interpreted as a positive reaction.

3.1.1.3. Infection with *Brucella* in pigs

As a diagnostic agent in pigs, 0.1 ml of the allergen suspension (2000 Units/ml) is injected intra-dermally into the skin at the base of the ear or preferably, next to the base of the tail. The latter appears more practical and less hazardous. The reaction is assessed by visual inspection and palpation of the inoculated area after 48 hours and a positive reaction is characterised by erythema of non-pigmented skin and an oedematous swelling. In some cases, there may also be some haemorrhage/necrosis.

3.2. Interferon gamma release assay

The interferon gamma release assay (IGRA) involves stimulation of lymphocytes in whole blood with a suitable antigen such as brucellin. The resulting gamma interferon production is detected through a capture ELISA. This test could be useful in the discrimination of brucellosis from FPSR but more specific antigens are still needed and the protocol needs to be standardised and properly validated in the different animal species and epidemiological conditions. For the moment, a fully validated protocol is not available.

C. REQUIREMENTS FOR VACCINES AND DIAGNOSTIC BIOLOGICALS

1. Vaccines

As mentioned previously, brucellosis is one of the most easily acquired laboratory infections, and strict safety precautions should be observed. Laboratory manipulation of live cultures of *Brucella,* including vaccine strains, is hazardous and must be performed at an appropriate biosafety and containment level determined by biorisk analysis (see Chapter 1.1.4). The S19, RB51 and Rev.1 vaccines have some virulence for humans, and a hazard warning should be included on the label of the final containers. Medical advice should be sought in the event of accidental inoculation or exposure (see Section C.1.2.3.2.3 Precautions) (Ashford *et al*., 2004; Joint FAO/WHO Expert Committee on Brucellosis, 1986; USDA, 2003).

1.1. Background

1.1.1. *Brucella abortus* strain 19 vaccine

A widely used vaccine for the prevention of brucellosis in cattle is *B. abortus* S19, which remains the reference vaccine with which any other vaccines must be compared. It is used as a live vaccine and is normally given to female calves aged between 3 and 6 months as a single subcutaneous dose of 5–8 × 10^{10} viable organisms. A reduced dose of from 3 × 10^{8} to 5 × 10^{9} organisms can be administered subcutaneously to adult cattle, but some animals can develop persistent antibody titres and may abort and excrete the vaccine strain in the milk. Alternatively, the vaccine can be administered to cattle of any age as either one or two doses of 5 × 10^{9} viable organisms, given by the conjunctival route. This vaccination procedure induces protection against both *B. abortus* (Nicoletti *et al*., 1978) and *B. melitensis* (Jimenez de Bagües *et al*., 1991) without a persistent antibody response and reduces the risks of abortion and excretion in milk when vaccinating adult cattle.

Brucella abortus S19 vaccine induces good immunity to moderate challenge by virulent *B. abortus* or *B. melitensis* organisms. The vaccine must be prepared from USDA-derived seed (see footnote 4 for address) and each batch must be checked for purity (absence of extraneous microorganisms), viability (live bacteria per dose) and smoothness (determination of dissociation phase). Seed lots for *B. abortus* S19 vaccine production should be regularly tested for residual virulence and immunogenicity in mice.

Control procedures for this vaccine are detailed in Section C.1.2.2.3 *In-process controls*.

1.1.2. *Brucella abortus* strain RB51 vaccine

Since 1996, *B. abortus* strain RB51 has become the official vaccine for prevention of brucellosis in cattle in several countries. However there is a disagreement over the protective performance of strain RB51 compared with strain S19 in cattle (Moriyon *et al*., 2004). Each country uses slightly different methods to apply this vaccine. In the USA (a country that was almost free of bovine brucellosis before RB51 was introduced), calves are vaccinated subcutaneously between the ages of 4 and 12 months with 1–3.4 × 10^{10} viable organisms. Vaccination of cattle over 12 months of age is carried out only under authorisation from the State or Federal Animal Health Officials, and the recommended dose is 1–3 × 10^{9} viable organisms (USDA, 2003). In other countries, it is recommended to vaccinate cattle as calves (4–12 months of age) with a 1–3.4 × 10^{10} dose, with revaccination from 12 months of age onwards with a similar dose to elicit a booster effect and increase immunity.

However, it has been reported that full doses of *B. abortus* strain RB51 when administered intravenously in cattle induce severe placentitis and placental infection in most vaccinated cattle, and that there is excretion in milk in a relevant number of vaccinated animals. Field experience also indicates that it can induce abortion and increased perinatal mortality if applied to pregnant cattle. These observations have led to the recommendation to avoid vaccination of pregnant cattle with *B. abortus* RB51. One way to reduce the side effects of *B. abortus* RB51 is to reduce the dose. When using the reduced dose of this vaccine (1 × 10^{9} colony-forming units [CFU]), on late pregnant cattle, no abortions or placentitis lesions have been reported, but the vaccine strain can be shed by a significant proportion of vaccinated animals. However, this reduced dose does not protect against *B. abortus* when used as a vaccine in calves, and the protection against *B. abortus*

is only moderate when used as an adult vaccine. The protection conferred by *B. abortus* RB51 against *B. melitensis* infection in cattle is unknown.

Control procedures for this vaccine are detailed in Section C.1.2.2.3.

1.1.3. *Brucella melitensis* strain Rev.1 vaccine

It is not infrequent to isolate *B. melitensis* in cattle in countries with a high prevalence of this infection in small ruminants (Verger, 1985). There has been some debate on the protective efficacy of *B. abortus* S19 against *B. melitensis* infection in cattle, but there is published evidence proving that this vaccine is able to control *B. melitensis* in cattle. It has been hypothesised that *B. melitensis* Rev.1 should be a more effective vaccine than *B. abortus* S19 in these conditions. However there is very little information related to this issue (Joint FAO/WHO Expert Committee on Brucellosis, 1986), and no experiments have been reported showing the efficacy of Rev.1 against *B. melitensis* infection in cows. Moreover, the safety of Rev.1 vaccine is practically unknown in cattle. Accordingly, until the safety of Rev.1 in cattle of different physiological status and efficacy studies against *B. melitensis* under strictly controlled conditions are performed, this vaccine should not be recommended for use in cattle.

Brucella melitensis Rev.1 is the most widely used vaccine for the prevention of brucellosis in sheep and goats, and, despite its drawbacks, remains the reference vaccine with which any other vaccines should be compared. By contrast, the rough *B. abortus* RB51 vaccine is not effective against *B. melitensis* infection in sheep. The Rev.1 vaccine is used as a freeze-dried suspension of live *B. melitensis* Rev.1 strain for the immunisation of sheep and goats. It should be given to lambs and kids aged between 3 and 5 months as a single subcutaneous or conjunctival inoculation, 5 months being the upper time limit to minimise the antibody response to make this vaccination compatible with further serological testing. No matter the inoculation route, the standard dose must be between 0.5×10^9 and 2.0×10^9 viable organisms. The reduced doses confer a significantly lower protection than the standard doses, and should not be recommended for vaccinating sheep and goats. The subcutaneous vaccination induces long-lasting serological responses, causing strong interferences in serological tests and should not be recommended for use in combined eradication programmes. However, when this vaccine is administered conjunctivally at the standard dose, it produces a similar protection without inducing a persistent antibody response, thus facilitating the application of eradication programmes combined with vaccination. Care must be taken when using *B. melitensis* Rev.1 vaccine to avoid the risk of contaminating the environment or causing human infection. In many developing countries and endemic areas, vaccination of the whole population has to be considered as the best option for the control of the disease (Blasco, 1997). However, Rev.1 vaccine is known to often cause abortion and excretion in milk when animals are vaccinated during pregnancy, either with a full or reduced dose (Blasco, 1997). These side-effects are considerably reduced when adult animals are vaccinated conjunctivally (full dose) during lambing/kidding, lactation or before mating. Therefore, when mass vaccination is the only means of controlling the disease, a vaccination campaign should be recommended using the standard dose of Rev.1 administered by the conjunctival route when the animals are not pregnant or during the late lambing/kidding and pre-breeding season (Blasco, 1997).

The subcutaneous vaccination of young animals and the vaccination of adult animals, even at reduced doses, may lead to long-term persistence of vaccinal antibodies in a significant proportion of Rev.1 vaccinated animals that creates serious interferences in the serological diagnosis of brucellosis. As indicated above, conjunctival vaccination minimises these problems (particularly when the upper limit of age for vaccination is 5 months) and thus it is the method of choice for combined eradication programmes. Therefore, the serological diagnosis of brucellosis should take into account the vaccinal state of the flock and the overall frequency distribution of antibody titres detected in the group of animals tested.

Control procedures for this vaccine are detailed in Section C.1.2.2.3.

1.1.4. Vaccination in pigs

Attempts have been made to develop a suitable vaccine to immunise pigs against *B. suis*, but none has been found fully effective. The live vaccine strain *B. suis* strain 2 (S2), produced in China

(People's Rep. of) by serial transfer of a virulent *B. suis* biovar 1 strain isolated from swine origin, has been widely used in that country (in pigs and other species), but efficacy data against *B. suis* infection under strictly controlled conditions are not available.

It is also reported that *B. abortus* strain RB51 vaccine is ineffective for the protection of swine against exposure to *B. suis* (Stoffregen *et al*., 2006).

1.1.5. Vaccination in other species

In wild species, differences in vaccine effects in wild and domestic species have been observed, particularly in the American bison (*Bison bison*) and elk (*Cervus canadensis*) regarding *B. abortus* (National Academies of Sciences, 2020) and in Alpine ibex using Rev.1 vaccination (Ponsart *et al*., 2019). The Rev.1 study suggests that in ibex, the Rev.1 vaccine strain persists longer at higher bacteriological levels (CFUs) than in goats. Given this discrepancy, it is very difficult to assess vaccine efficacy in wild species based on experiments done in domestic species. Injection route, type and dose of vaccines should be systematically assessed including an infection challenge.

1.2. Outline of production and requirements

1.2.1. Characteristics of the seed

1.2.1.1. Biological characteristics of the master seed

Brucella abortus S19 original seed for vaccine production must be obtained from the USDA (see footnote 4 for address), and used to produce a seed lot that is preserved by lyophilisation or by freezing at liquid nitrogen temperature. The properties of this seed lot must conform to those of a pure culture of a CO_2-independent *B. abortus* bv. 1 that is also sensitive to benzyl-penicillin (3 μg [5 IU]/ml), thionin blue (2 μg/ml) and i-erythritol (1 mg/ml), and that displays minimal pathogenicity for guinea-pigs.

Brucella abortus RB51 original seed for vaccine production is available commercially. It is also obtainable from the USDA (see footnote 4 for address). *Brucella abortus* RB51 has the normal properties of a bv. 1 strain of *B. abortus*, but is 100% in the rough phase and does grow in the presence of rifampicin (250 μg/ml).

Brucella melitensis strain Rev.1 original seed for vaccine production can be obtained commercially. A European reference Rev.1 strain that possesses the characteristics of the Rev.1 original seed is also obtainable from the WOAH Reference Laboratory for Brucellosis in France. Strain Rev.1 must conform to the characteristics of *B. melitensis* bv. 1, except that it should grow more slowly. Additionally, when incubated in air (atmospheres containing CO_2 alter the results) at 37°C± 2°C, it should grow on agar containing streptomycin (2.5 μg/ml), and it should be inhibited by the addition to a suitable culture medium of sodium benzyl-penicillin (3 μg [5 IU]/ml), thionin (20 μg/ml) or basic fuchsin (20 μg/ml).

PCR and molecular techniques have been used to further characterise the S19, RB51 or Rev.1 vaccines (see Section B.1.4).

The specific requirements for S19 and Rev.1 vaccine production recommend that each seed lot (i.e. the culture used to inoculate medium for vaccine production) should be no more than three passages removed from an original seed culture and that the harvest of a vaccine lot should be no more than three passages from a seed lot or an original seed. The original seed culture should always be checked for the absence of dissociation before use. The recommended method for preparing seed material is given in Alton *et al*. (1988).

1.2.1.2. Quality criteria

Brucella abortus S19 and RB51 as well as *B. melitensis* Rev.1 master seeds should be checked for purity, identity and, where appropriate, smoothness or roughness. S19 and Rev.1 seed lots must also conform to the characteristics of residual virulence and immunogenicity in mice of the original seed.

1.2.1.2.1. Purity

Tests for purity and freedom from contamination of biological materials may be found in Chapter 1.1.9 *Tests for sterility and freedom from contamination of biological materials intended for veterinary use*.

1.2.1.2.2. Safety

The S19 and Rev.1 vaccines show reduced virulence, but should keep a minimal virulence to be efficient (see Section C.1.2.1.2.3 *Potency*). However a safety test is not routinely done. If desired, when a new manufacturing process is started and when a modification in the innocuousness of the S19 and Rev.1 vaccine preparations is expected, it may be performed on cattle (S19) and sheep and goats (Rev.1). This control should be done as follows: the test uses 12 female calves or sheep/goats respectively, aged 4–6 months. Six young females are injected with one or three recommended doses. Each lot of six young females are kept separately. All animals are observed for 21 days. No significant local or systemic reaction should occur. If, for a given dose and route of administration, this test gives good results on a representative batch of the vaccine, it does not have to be repeated routinely on seed lots or vaccine lots prepared with the same original seed and with the same manufacturing process. A safety test on S19/Rev.1 vaccine may also be performed in guinea-pigs. Groups of at least ten animals are given intramuscular injections of doses of vaccine diluted in PBS, pH 7.2 ± 0.2, to contain 5×10^9 viable organisms. The animals should show no obvious adverse effects and there must be no mortality.

If this safety test has been performed with good results on a representative seed lot or batch of the test vaccine, it does not have to be repeated routinely on other vaccine lots prepared from the same seed lot and using the same manufacturing process.

If a safety test for RB51 is desired, 8- to 10-week-old female Balb/c mice can be injected intraperitoneally with 1×10^8 CFUs and the spleens cultured at 6 weeks post-inoculation. Spleens should be free from RB51 and the mice should not develop anti-OPS antibodies.

1.2.1.2.3. Potency

i) S19 vaccine

An S19 vaccine is effective if it possesses the characteristics of the S19 original strain, i.e. if it is satisfactory with respect to identity and smoothness. Moreover, it should have been produced with a given seed lot with adequate immunogenicity and residual virulence (Grillo *et al*., 2000).

a) Identity

Brucella abortus present in the vaccine is identified by suitable morphological, serological and biochemical tests and by culture: *B. abortus* S19 has the normal properties of a *B. abortus* bv. 1 strain of, but does not require CO_2 for growth, does not grow in the presence of benzyl-penicillin (3 μg/ml = 5 IU/ml), thionin blue (2 μg/ml), and i-erythritol (1 mg/ml) (all final concentrations). PCR and molecular techniques have been described to identify the S19 vaccine strain (see Section B.1.4).

b) Smoothness (determination of dissociation phase)

The S19 vaccine reconstituted in purified water is streaked across six agar plates (serum–dextrose agar or trypticase–soy agar (TSA) with added serum 5% [v/v] or yeast extract 0.1 % [w/v) in such a manner that the colonies will be close together in certain areas, while semi-separated and separated in others. Slight differences in appearance are more obvious in adjacent than widely separated colonies. Plates are incubated at 37°C ± 2°C for 5 days and examined by obliquely reflected light (Henry's method) before and after staining (three plates) with crystal violet (White & Wilson's staining method).

Appearance of colonies before staining: S colonies appear round, glistening and blue to blue–green in colour. R colonies have a dry, granular appearance and are dull yellowish–white in colour. Mucoid colonies (M) are transparent and greyish in colour and can be distinguished by their slimy consistency when touched with a loop. Intermediate colonies (I), which are the most difficult to classify, have an appearance intermediate between S and R forms: they are slightly opaque and more granular than S colonies.

Appearance of colonies after staining with crystal violet: S colonies do not take up the dye. Dissociated colonies (I, M, or R) are stained various shades of red and purple and the surface may show radial cracks. Sometimes a stained surface film slips off a dissociated colony and is seen adjacent to it.

The colony phase can be confirmed by the acriflavine agglutination test (Alton *et al*., 1988). S colonies remain in suspension, whereas R colonies are agglutinated immediately and, if mucoid, will form threads. Intermediate colonies may remain in suspension or a very fine agglutination may occur.

At least 99% of cells in seed lots should be in the smooth phase.

c) Residual virulence (50% persistence time or 50% recovery time) (Grillo *et al*., 2000; Pouillot *et al*., 2004)

1) Prepare adequate suspensions of either the *B. abortus* S19 seed lot to be tested (test vaccine) and the S19 original seed culture (as a reference strain). For this, harvest 24–48 hours' growth of each strain in sterile buffered saline solution (BSS: NaCl 8.5 g; KH_2PO_4 1.0 g; K_2HPO_4 2.0 g; purified water 1000 ml; pH 6.8 ± 0.2) and adjust the suspension in BSS to 10^9 CFU/ml using a spectrophotometer (0.170 OD when read at 600 nm). The exact number of CFU/ml should be checked afterwards by plating serial tenfold dilutions on to adequate culture medium (blood agar base or TSA are recommended).

2) Inject subcutaneously 0.1 ml (10^8 CFU/mouse) of the suspension containing the test vaccine into each of 32 female CD1 mice, aged 5–6 weeks. Carry out, in parallel, a similar inoculation in another 32 mice using the suspension containing the S19 reference strain. The original seed S19 strain, which has been shown satisfactory with respect to immunogenicity and/or residual virulence, can be obtained from USDA (see footnote 4 for address).

3) Kill the mice by cervical dislocation, in groups of eight selected at random 3, 6, 9 and 12 weeks later.

4) Remove the spleens and homogenise individually and aseptically with a glass grinder (or in adequate sterile bags with a paddle blender) in 1 ml of sterile BSS.

5) Spread each whole spleen suspension *in toto* onto several plates containing a suitable culture medium and incubate in standard *Brucella* conditions for 5–7 days (lower limit of detection: 1 bacterium per spleen). An animal is considered infected when at least 1 CFU is isolated from the spleen.

6) Calculate the 50% persistence time or 50% recovery time (RT_{50}) by a statistical method specifically developed for RT_{50} calculations[6]. For this, determine the number of cured mice (no colonies isolated in the spleen) at each slaughtering point time (eight mice per point) and calculate the percentage of cured accumulated mice over time, by the Reed and Muench method (see ref. cited in Grillo *et al*., 2000). The function of distribution of this percentage describes a sigmoid curve, which must be linearised for calculating the RT_{50} values, using the computerised PROBIT procedure of the statistical package.

6 To obtain details of the software contact the WOAH Reference Laboratory for brucellosis in France.

7) Compare statistically the parallelism (intercept and slope) between the distribution lines obtained for both tested and reference S19 strains using the software specifically designed for this purpose. Two RT_{50} values can be statistically compared exclusively when they come from parallel distribution lines. If parallelism does not exist, the residual virulence of the tested strain should be considered inadequate, and discarded for vaccine production.

8) If the parallelism is confirmed, compare statistically the RT_{50} values obtained for both tested and reference S19 strains using the software specifically designed for this purpose. To be accepted for vaccine production, the RT_{50} obtained with the tested strain should not differ significantly from that obtained with the reference S19 strain (RT_{50} and confidence limits are usually around 7.0 ± 1.3 weeks).

The underlying basis of the statistical procedure for performing the above residual virulence calculations have been described in detail (see ref. cited in Grillo *et al*., 2000). Alternatively, the statistical calculations described in steps 6 to 8 above can be avoided by an easy-to-use specific HTML-JAVA script program (Rev2) available free from the WOAH Reference Laboratory in France (Pouillot *et al*., 2004).

If this test has been performed with good results on a representative seed lot, it does not have to be repeated routinely on other seed lots and vaccine batches prepared from the same seed strain and using the same manufacturing process.

d) Immunogenicity in mice (Grillo *et al*., 2000)

This test uses three groups of six female CD1 mice, aged 5–7 weeks that have been selected at random.

1) Prepare and adjust spectrophotometrically the vaccine suspensions as indicated above.

2) Inject subcutaneously a suspension containing 10^5 CFU (in a volume of 0.1 ml/mouse) of the vaccine to be examined (test vaccine) into each of six mice of the first group.

3) Inject subcutaneously a suspension containing 10^5 CFU of live bacteria of a reference S19 vaccine into each of six mice of the second group. The third group will serve as the unvaccinated control group and should be inoculated subcutaneously with 0.1 ml of BSS.

4) The exact number of CFU inoculated should be checked afterwards by plating serial tenfold dilutions onto adequate culture medium (blood agar base or TSA are recommended).

5) All the mice are challenged 30 days after vaccination (and immediately following 16 hours starvation), intraperitoneally with a suspension (0.1 ml/mouse) containing 2×10^5 CFU of *B. abortus* strain 544 (CO_2-dependent), prepared, adjusted and retrospectively checked as above.

6) Kill the mice by cervical dislocation 15 days later.

7) Each spleen is excised aseptically, the fat is removed, and the spleen is weighed and homogenised.

8) Alternatively, the spleens can be frozen and kept at ≤ –16°C for 24 hours to 7 weeks.

9) Each spleen is homogenised aseptically with a glass grinder (or in adequate sterile bags in Stomacher) in nine times its weight of BSS, pH 6.8 ± 0.2 and three serial tenfold dilutions (1/10, 1/100 and 1/1000) of each homogenate made in the same diluent. Spread 0.2 ml of each dilution by quadruplicate in agar plates and incubate two of the plates in a 10% CO_2 atmosphere (allows the growth of both vaccine and challenge strains) and the other two

plates in air (inhibits the growth of the *B. abortus* 544 CO_2-dependent challenge strain), both at 37°C± 2°Cfor 5 days.

10) Colonies of *Brucella* (*B. abortus* 544) should be enumerated on the dilutions corresponding to plates showing fewer than 300 CFU. When no colony is seen in the plates corresponding to the 1/10 dilution, the spleen is considered to be infected with five bacteria. These numbers of *Brucella* per spleen are first recorded as X and expressed as Y, after the following transformation: Y = log (X/log X). Mean and standard deviation, which are the response of each group of six mice, are then calculated.

11) The conditions of the control experiment are satisfactory when: i) the response of unvaccinated mice (mean of Y) is at least of 4.5; ii) the response of mice vaccinated with the reference S19 vaccine is lower than 2.5; and iii) the standard deviation calculated on each lot of six mice is lower than 0.8.

12) Carry out the statistical comparisons (the least significant differences test is recommended) of the immunogenicity values obtained in mice vaccinated with the S19 strain to be tested with respect to those obtained in mice vaccinated with the reference vaccine and in the unvaccinated control group. The test vaccine would be satisfactory if the immunogenicity value obtained in mice vaccinated with this vaccine is significantly lower than that obtained in the unvaccinated controls and, moreover, does not differ significantly from that obtained in mice vaccinated with the reference vaccine (for detailed information on this procedure, see the WOAH Reference Laboratory in France).

If this test has been performed with good results on a representative seed lot, it does not have to be repeated routinely on other seed lots and vaccine batches prepared from the same seed strain and with the same manufacturing process.

ii) RB51 vaccine

An RB51 vaccine seed lot must possess the characteristics of the RB51 original strain, i.e. if it is satisfactory with respect to identity, roughness and potency.

a) Identity

The reconstituted RB51 vaccine should not contain extraneous microorganisms. *Brucella abortus* present in the vaccine is identified by suitable morphological, serological and biochemical tests and by culture: *B. abortus* RB51 has the normal properties of a *B. abortus* bv. 1 strain, but is 100% in the rough phase and does grow in the presence of rifampicin (250 μg/ml). PCR and molecular techniques have been described to further characterise the RB51 vaccine strain (see Section B.1.4).

b) Roughness (determination of dissociation phase)

The same technical procedures indicated for S19 vaccine (see Section C. 1.2.1.2.3.i *S19 vaccine* above) have to be applied for RB51. 100% of the RB51 cells must be in the rough phase. Additionally, for RB51, all colonies should be negative on dot-blot assays with MAbs specific for the OPS antigen.

c) Potency

As dosage (CFU) of the master seed was correlated to protection as part of registration of RB51 for use cattle in the USA, *in-vivo* potency tests are not routinely conducted for serials of the RB51 vaccine. In the USA, plate counts of viable organisms have been approved and used as a measure of potency (this approach is identical to the potency test for S19 vaccine in the USA (USDA, 2003). Rough vaccines for brucellosis have been discussed in some detail (Moriyon *et al*., 2004).

iii) Rev.1 vaccine

A Rev.1 vaccine is efficient if it possesses the characteristics of the Rev.1 original strain, i.e. if it is satisfactory with respect to identity and smoothness. Moreover, it should have been produced with a given seed lot with adequate immunogenicity, and residual virulence (Grillo *et al*., 2000).

a) Identity

Brucella melitensis present in the vaccine is identified by suitable morphological, serological and biochemical tests and by culture: when incubated in air at 37°C ± 2°C, Rev.1 strain is inhibited by addition to the suitable culture medium of 3 µg (5 IU) per ml of sodium benzyl-penicillin, thionin (20 µg/ml) or basic fuchsin (20 µg/ml); the strain grows on agar containing 2.5 µg per ml of streptomycin. PCR and molecular techniques have been described to further characterise the Rev.1 vaccine strain (see Section B.1.4).

b) Smoothness (determination of dissociation phase)

The same technical procedures indicated for S19 vaccine (Section C. 1.2.1.2.3.i above) have to be applied for Rev.1.

Sometimes, slight and difficult to observe differences can be seen in the size of Rev.1 colonies. The small colonies (1–1.2 mm in diameter) are typical for Rev.1, but larger Rev.1 colonies can appear depending on the medium used, the amount of residual moisture in the incubator atmosphere, and the presence or absence of CO_2. The frequency of variation in colony size occurs normally at a ratio of 1 large to 10^3 small colonies. Both Rev.1 variants are of the S (smooth) type. To avoid an increase in this colony size variation along successive passages, it is important to always select small colonies for preparation of seed lots.

At least 99% of cells in seed lots should be in the smooth phase.

c) Residual virulence (50% persistence time or 50% recovery time) (Grillo *et al*., 2000)

The same technical procedures indicated for RT_{50} calculation of S19 vaccine (see above) have to be applied for Rev.1, except that *B. abortus* S19 seed lot to be tested (test vaccine) and the S19 original seed culture (used as a reference strain), respectively, are replaced by the corresponding *B. melitensis* Rev.1 seed lot to be tested (test vaccine) and the *B. melitensis* Rev.1 original seed culture as the reference strain. For the reference original Rev.1 strain, RT_{50} and confidence limits are around 7.9 ± 1.2 weeks. A given Rev.1 vaccine seed lot or batch should keep similar residual virulence to be acceptable.

If this test has been done with good results on a representative seed lot, it does not have to be repeated routinely on seed lots and vaccine batches prepared from the same seed strain and with the same manufacturing process.

d) Immunogenicity in mice

The same technical procedures indicated for immunogenicity calculation of S19 vaccine (see above) have to be applied for Rev.1, except that *B. abortus* S19 seed lot to be tested (test vaccine) and the *B. abortus* S19 original seed culture (used as a reference strain), respectively, are replaced by the corresponding *B. melitensis* Rev.1 seed lot to be tested (test vaccine) and the *B. melitensis* Rev.1 original seed culture as the reference strain.

Conditions of the control experiment are satisfactory when: i) the response in unvaccinated mice (mean of Y) is at least of 4.5; ii) the response in mice vaccinated with the reference Rev.1 vaccine is lower than 2.5; and iii) the standard deviation calculated on each lot of six mice is lower than 0.8.

If this test has been done with good results on a representative seed lot, it does not have to be repeated routinely on seed lots and vaccine batches prepared from the same seed strain and with the same manufacturing process.

1.2.1.3. Validation as a vaccine

Numerous independent studies have confirmed the value of S19 as a vaccine for protecting cattle from brucellosis, and it has been the vaccine used (in combination with serological testing and culling) to eradicate bovine brucellosis in most currently free countries. The organism behaves as an attenuated strain when given to sexually immature cattle. In rare cases, when standard doses are applied subcutaneously, it may produce localised infection in the genital tract particularly in males. For this reason, vaccination of males is contra-indicated. Antibody responses persisting for 6 months or longer are likely to occur in a substantial proportion of cattle that have been vaccinated subcutaneously with the standard dose as adults. Some of the cattle vaccinated subcutaneously as calves may later develop arthropathy, particularly of the femoro-tibial joints. The vaccine is safe for most animals if administered to calves between 3 and 6 months of age. It may also be used in adult animals at a reduced dose, with the advantage of reducing the diagnostic interferences. It produces lasting immunity to moderate challenge with virulent *B. abortus* strains, but the precise duration of this immunity is not well known. The length of protection of this vaccine against *B. melitensis* infection in cattle is also unknown. The vaccine strain is stable and reversion to virulence is extremely rare. It has been associated with the emergence of i-erythritol-using strains when inadvertently administered to pregnant animals. The organism behaves as an attenuated strain in mice, and even large inocula are rapidly cleared from the mice tissues.

Reports from both experimental challenge studies and field studies remain controversial as far as the value of *B. abortus* strain RB51 in protecting cattle from brucellosis is concerned (see above). The organism is attenuated in calves but can cause safety problems in adults. *Brucella abortus* strain RB51 contains minimally expressed OPS but there is no serological conversion in both standard RBT and CFT in vaccinated animals. In addition, it has also been claimed that RB51 does not induce detectable antibodies, using current OPS-based testing procedures (USDA, 2003). However, the presence of common core epitopes in both smooth and rough *Brucella* does not allow always the antibody response to RB51 to be distinguished from that induced by field smooth *Brucella* strains, no matter which S-LPS or OPS-based ELISA is used (Gusi *et al*., 2019). The efficacy of RB51 against *Brucella* infection in cattle is controversial (Moriyon *et al*., 2004), but it is claimed that it protects against moderate challenge with virulent *B. abortus*, although the precise duration of this protection is unknown. The efficacy of this vaccine against *B. melitensis* infection in cattle is also unknown. The vaccine is very stable and no reversion to smoothness has been described *in vivo* or *in vitro*. The organism behaves as an attenuated strain in a variety of animals including mice where it is rapidly cleared from the tissues.

Numerous independent studies have confirmed the value of *B. melitensis* strain Rev.1 as a vaccine for protecting sheep and goats from brucellosis. Its virulence is unchanged after passage through pregnant sheep and goats. However, abortions and excretion in milk may result when the Rev.1 vaccine is inoculated into pregnant ewes and goats. The vaccine-induced abortions are not avoided using reduced doses and doses as low as 10^6, used either subcutaneously or conjunctivally in pregnant animals, have been proven to induce abortions and milk excretion of the vaccine strain (Blasco, 1997).

1.2.2. Method of manufacture

1.2.2.1. Procedure

Production of *Brucella* live vaccines is based on the seed-lot system described above (Section B.2.2) for BBAT and CFT antigens.

For the production of S19 vaccine, the procedures described above can be used, except that the cells are collected in PBS, pH 6.3 ± 0.2, and deposited by centrifugation or by the addition of sodium carboxymethyl cellulose at a final concentration of 1.5 g/litre. The yield from one fermenter run or the pooled cells from a batch of Roux flask cultures that have been

inoculated at the same time from the same seed lot constitutes a single harvest. More than one single harvest may be pooled to form a final bulk, which is used to fill the final containers of a batch of vaccine. Before pooling, each single harvest must be checked for purity, cell concentration, dissociation and identity. A similar range of tests must be done on the final bulk, which should have a viable count of between 8 and 24 × 10^9 CFU/ml. Adjustments in concentration are made by the addition of PBS for vaccine to be dispensed in liquid form, or by the addition of stabiliser for lyophilised vaccine. If stabiliser is to be used, loss of viability on lyophilisation should be taken into account, and should not be in excess of 50%. The final dried product should not be exposed to a temperature exceeding 35°C during drying, and the residual moisture content should be 1–2%. The contents must be sealed under vacuum or dry nitrogen immediately after drying, and stored at 5°C ± 3°C.

The production process for *B. abortus* strain RB51 is very similar to the one used for S19.

For the production of *B. melitensis* strain Rev.1 vaccine, the procedures described above for antigens (Alton *et al*., 1988) can be used except that the cells are collected in a freeze-drying stabiliser and deposited by centrifugation. The yield from one fermenter run or the pooled cells from a batch of Roux flask cultures inoculated on the same occasion from the same seed lot constitutes a single harvest. More than one single harvest may be pooled to form the final bulk that is used to fill the final containers of a batch of vaccine. Before pooling, each single harvest must be checked for purity, cell concentration, dissociation and identity. The volume of the final bulk is adjusted by adding sufficient stabiliser so that a dose contains an appropriate number of viable organisms. After adjusting the cell concentration of the final bulk, tests for identity, dissociation and absence of contaminating organisms are conducted (see below).

1.2.2.2. Requirements for ingredients

Strains should be cultured in a suitable medium.

Brucella abortus S19 and *B. melitensis* strain Rev.1 for vaccine production is grown on medium free from serum or other animal products, under conditions similar to those described above for *B. abortus* S99 or S1119-3 (Alton *et al*., 1988). The phenol saline is replaced by a freeze-drying stabiliser.

Brucella abortus strain RB51 follows similar culture methods.

Serum–dextrose agar, and trypticase–soy agar, to which 5% serum or 0.1% yeast extract may be added, are among the solid media that have been found to be satisfactory for propagating the Rev.1 strain (Alton *et al*., 1988). However, Rev.1 strain does not grow well on potato agar and generally needs 3–5 days to grow.

For all vaccines, the organisms are not killed but are stored at 5°C ± 3°C while quality control examinations are carried out as described below.

For preparation of the lyophilised vaccine, a stabiliser containing 2.5% casein digest, e.g. Tryptone (Oxoid), 5% sucrose and 1% sodium glutamate, dissolved in purified water and sterilised by filtration is recommended.

Antimicrobial preservatives must not be used in live *B. abortus* strain S19 or RB51 and *B. melitensis* strain Rev.1 vaccines.

1.2.2.3. In-process controls

Brucella abortus S19 and RB51 as well as *B. melitensis* Rev.1 vaccines should be checked for purity, identity and, where appropriate, smoothness or roughness during preparation of the single harvests. The cell concentration of the bulks should also be checked. This can be done by opacity measurement, but a viable count must be performed on the final filling lots. The identity of these should also be checked by agglutination tests with antiserum to either *Brucella*-A, -R or -M antigen respectively.

The viable count of the final containers should not be less than the recommended doses (see above).

For S19 and Rev.1, at least 99% of cells in seed lots and 95% of cells in final lots should be in the smooth phase, while 100% of the RB51 cells must be in the rough phase. Additionally, for RB51, all colonies should be negative on dot-blot assays with monoclonal antibodies specific for the OPS antigen.

For S19 and Rev.1, the immunogenicity and the residual virulence (50% persistence time or 50% recovery time) in the mice model should also be determined on representative seed lots. If these tests have been done with good results on a representative seed lot, it does not have to be repeated routinely on seed lots and vaccine batches prepared from the same seed strain and with the same manufacturing process.

1.2.2.4. Final product batch tests

With freeze-dried vaccine, the control tests should be conducted on the vaccine reconstituted in the form in which it will be used (same diluent).

1.2.2.4.1. Purity

Tests for purity and freedom from contamination of biological materials may be found in chapter 1.1.9.

1.2.2.4.2. Identity

See Section C.1.2.1.2.3 *Potency*.

1.2.2.4.3. Safety

See Section C.1.2.1.2.2 *Safety*.

1.2.2.4.4. Batch potency

i) Potency

For S19 and Rev.1 vaccines, potency can also be determined on the final lyophilised product. The procedure is as described above (identity; smoothness; residual virulence and immunogenicity checks; see Section C.1.2.1.2.3.). If residual virulence and immunogenicity checks have been performed with good results on a representative batch of the test vaccine, they do not have to be repeated routinely on other vaccine lots prepared from the same seed lot and using the same manufacturing process.

ii) Enumeration of live bacteria

Batches should also be checked for the number of viable organisms. The same procedure may be applied for the S19, Rev.1 and RB51 vaccine batches. Inoculate each of at least five plates of tryptose, serum-dextrose or other suitable agar medium with 0.1 ml of adequate dilutions of the vaccine spread with a sterile glass, wire or plastic spreader. CFU per vaccine volume unit are enumerated.

Suitable CFU counts are the following:

S19:

a) $0.5–1 \times 10^{11}$ CFU (standard dose; subcutaneous route);

b) $0.5–5 \times 10^{9}$ CFU (reduced dose; subcutaneous route);

c) 5×10^{9} CFU (reduced dose; conjunctival route).

Rev.1:

a) $0.5–2 \times 10^{9}$ CFU (standard dose, subcutaneous or conjunctival route).

RB51:

a) 1–3.4 × 10^{10} CFU (standard dose; subcutaneous route).

1.2.3. Requirements for regulatory approval

1.2.3.1. Manufacturing process

For regulatory approval of the vaccine, all relevant details concerning manufacture of the vaccine and quality control testing (see above) should be submitted to the authorities. This information should be provided from three consecutive vaccine batches with a volume of not less than 1/3 of the typical industrial batch volume.

1.2.3.2. Safety requirements

1.2.3.2.1. Target and non-target animal safety

For the potential side-effects of the *Brucella* vaccines according to the status of the animals, see Section C.1.1. *Background*.

1.2.3.2.2. Reversion-to-virulence

Brucella abortus S19 and *B. melitensis* Rev.1 vaccines prepared from seed stock from appropriate sources are stable in characteristics, provided that the in-process and batch control requirements described above are fulfilled, and show no tendency to reversion to virulence.

Brucella abortus strain RB51 has shown no tendency to revert to virulent smooth organisms after many passages *in vitro* or *in vivo*. This is probably due to the nature and place of the mutations found in this strain. *Brucella abortus* strain RB51, despite carrying, among other unknown mutations, an IS711-disrupted *wbo*A (a putative glycosyl-tranferase gene), accumulates low amounts of cytoplasmic M-like OPS.

1.2.3.2.3. Precautions

Brucella abortus S19 and RB51, as well as *B. melitensis* Rev.1, although attenuated strains, are still capable of causing disease in humans. Accordingly cell cultures and suspensions must be handled under appropriate conditions of biohazard containment (see chapter 1.1.4). Reconstitution and subsequent handling of the reconstituted vaccine should be done with care to avoid accidental injection or eye or skin contamination. Vaccine residues and injection equipment should be decontaminated with a suitable disinfectant (phenolic, iodophor or aldehyde formulation) at recommended concentration. Medical advice should be sought in the event of accidental exposure. The efficacy of the antibiotic treatment of infections caused by S19, RB51 or Rev.1 in humans has not been fully established. However, it must be reiterated that, while the S19 strain carries no particular antibiotic resistance compared with other *Brucella* field strains, Rev.1 and RB51 strains are respectively streptomycin- and rifampicin-resistant.

Vaccine should be identified as pathogenic for vaccinators. Manufacturers should provide adequate warnings that medical advice should be sought in the case of self-injection or exposure to vaccine (including aerosols) with warnings included on the product label/leaflet so that the vaccinator is aware of any danger.

1.2.3.3. Efficacy requirements

Potency can also be determined on the final batch, but if safety/efficacy tests have been performed with good results on a representative seed lot or a batch of the test vaccine, it does not have to be repeated routinely on other vaccine lots prepared from the same seed lot and using the same manufacturing process.

1.2.3.4. Duration of immunity

Vaccinating calves with a full dose of S19 vaccine is considered to give long-lasting immunity, and subsequent doses are not recommended. However, there is scanty evidence for this and revaccination within 6–12 months could be advisable in endemic areas.

The duration of immunity induced by RB51 vaccine in cattle is unknown, whatever the dose applied and the age at vaccination. Revaccination within 6–12 months has been proposed for boosting immunity in endemic areas.

It is accepted that subcutaneous or conjunctival vaccination with standard doses of Rev.1 confers a solid and durable immunity in sheep and goats. However, growing field evidence shows that the immunity conferred declines with time, and revaccination within 6–12 months could be advisable in endemic areas.

1.2.3.5. Stability

Brucella abortus S19 and *B. melitensis* Rev.1 vaccines prepared from seed stock from appropriate sources are stable in characteristics, provided that the in-process and batch control requirements described above are fulfilled, and show no tendency to reversion to virulence. The lyophilised vaccine shows a gradual loss of viable count, but should retain its potency for the recommended shelf life. Allowance for this phenomenon is normally made by ensuring that the viable count immediately following lyophilisation is well in excess of the minimum requirement. Maintenance of a cold chain during distribution of the vaccine will ensure its viability.

Brucella abortus strain RB51 has shown no tendency to revert to virulent smooth organisms after many passages *in vitro* or *in vivo*. This is probably due to the nature and place of the mutations found in this strain. *Brucella abortus* strain RB51, despite carrying, among other unknown mutations, an IS711-disrupted *wbo*A (a putative glycosyl-tranferase gene), accumulates low amounts of cytoplasmic M-like OPS.

2. Diagnostic biologicals: brucellin

2.1. Background

Brucellin-INRA is an LPS-free extract from rough *B. melitensis* B115, and a single inoculation of this preparation does not provoke formation of antibodies reactive in BBAT, CFT or ELISAs. However, as this rough strain contains *Brucella* OPS sugars in the cytosol extract, the repeated inoculation of brucellin could elicit antibodies, interfering with other diagnostic tests. For this reason, cytosolic protein extracts have been obtained from rough *B. abortus* mutants, defective in genes strictly necessary to synthesise perosamine, and therefore unable to generate OPS antibody response in sheep.

2.2. Outline of production and requirements

2.2.1. Characteristics of the seed

2.2.1.1. Biological characteristics of the master seed and quality criteria

Production of brucellin-INRA is based on a seed-lot system as described for antigens and vaccines. The original seed *B. melitensis* strain B115 for brucellin production[5] should be propagated to produce a seed lot, which should be preserved by lyophilisation or freezing at liquid nitrogen temperature. It should conform to the properties of a pure culture of a rough strain of *B. melitensis* and must not produce smooth *Brucella* LPS. It should produce reasonable yields of a mixture of protein antigens reactive with antisera to smooth and rough *Brucella* strains.

2.2.1.2. Quality criteria

Brucella melitensis B115 seed should be checked for purity.

Tests for purity and freedom from contamination of biological materials may be found in chapter 1.1.9.

2.2.1.3. Validation as an *in-vivo* diagnostic reagent

Laboratory and field studies in France have confirmed that brucellin-INRA is safe, non-toxic and specific in action. The preparation contains 50–75% proteins, mainly of low molecular weight, and 15–30% carbohydrate. It does not contain S-LPS antigens, does not provoke inflammatory responses in unsensitised animals, and it is not in itself a sensitising agent. After a single inoculation, it does not induce detectable antibodies in the standard serological tests for brucellosis. More than 90% of small ruminants infected with *B. melitensis* manifest delayed hypersensitivity to brucellin-INRA at some stage. The preparation is not recommended as a diagnostic agent for individual animals, but can be useful when used for screening herds. It is given to small ruminants in 100-µg doses by the intradermal route, and provokes a local delayed hypersensitivity reaction visible at 48–72 hours in sensitised animals. Positive reactions can be given by vaccinated as well as by infected animals (Pouillot *et al*., 1997).

2.2.2. Method of manufacture (Alton *et al*., 1988)

2.2.2.1. Procedure and requirements for ingredients

Brucellin is produced from *B. melitensis* strain B115 according to Alton *et al*., 1988.

2.2.2.2. In-process control

The crude brucellin extract should be checked for sterility after acetone extraction, to ensure killing of *Brucella* cells, and again at the end of the process to check possible contamination. The pH and protein concentration should be determined, and control tests (as described in Section C.2.2.2.3 below) should be performed on the bulk material before filling the final containers.

2.2.2.3. Final product batch tests

i) Sterility

Brucellin preparations should be checked for sterility as described in chapter 1.1.9.

ii) Safety

Brucellin preparations should also be checked for abnormal toxicity. Doses equivalent to 20 cattle doses (2 ml) should be injected intraperitoneally into a pair of normal guinea-pigs that have not been exposed previously to *Brucella* organisms or their antigens. Five normal mice are also inoculated subcutaneously with 0.5 ml of the brucellin (2000 U/ml) to be examined. Animals are observed for 7 days, and there should be no local or generalised reaction to the injection.

Dermo-necrotic capacity is examined by intradermal inoculation of 0.1 ml of the product to be tested into the previously shaved and disinfected flank of three normal albino guinea-pigs that have not been exposed previously to *Brucella* organisms or their antigens. No cutaneous reaction should be observed.

Absence of allergic and serological sensitisation is checked by intradermal inoculation of three normal albino guinea-pigs, three times every 5 days, with 0.1 ml of a 1/10 dilution of the preparation to be examined. A fourth similar injection is given, 15 days later, to the same three animals and to a control lot of three guinea-pigs of the same weight that have not been injected previously. The animals should not become seropositive to the standard tests for brucellosis (RBT, CFT) when sampled 24 hours after the last injection, and should not develop delayed hypersensitivity responses.

iii) Batch potency

The potency of brucellin preparations is determined by intradermal injection of graded doses of brucellin into guinea-pigs that have been sensitised by subcutaneous inoculation

of 0.5 ml of reference brucellin[7] in Freund's complete adjuvant from 1 to 6 months previously (the use of a live *Brucella* strain, for example Rev.1 strain, is possible provided that it produces the same level of sensitisation). The erythematous reactions are read and measured at 24 hours and the titre is calculated by comparison with a reference brucellin[8]. This method is only valid for comparing brucellin preparations made according to the same protocol as the sensitising allergen. Initial standardisation of a batch of allergen and the sensitisation and titration in ruminants is described (Alton *et al*., 1988).

2.2.3. Requirements for regulatory approval

2.2.3.1. Manufacturing process

For regulatory approval of the brucellin, all relevant details concerning manufacture of the product and quality control testing (see above) should be submitted to the regulatory authorities in accordance with their requirements. This information should be provided from three consecutive product batches with a volume of not less than 1/3 of the typical industrial batch volume.

2.2.3.2. Safety requirements

i) Target and non-target animal safety

No side-effects of the brucellin have ever been reported in animals.

ii) Reversion-to-virulence

Not applicable.

iii) Precautions

Brucellin is not toxic. Nevertheless it may provoke severe hypersensitivity reactions in sensitised individuals who are accidentally exposed to it. Care should be taken to avoid accidental injection or mucosal contamination. Used containers and injection equipment should be carefully decontaminated or disposed of by incineration in a suitable disposable container.

Brucellin should be identified as potentially harmless for practitioners. Manufacturers should provide adequate warnings that medical advice should be sought in the case of self-injection or mucosal exposure with warnings included on the product label/leaflet so that the practitioner is aware of any danger.

2.2.3.3. Efficacy requirements

Potency must be determined on the final product. The procedure is as described above.

2.2.3.4. Duration of sensitivity

Duration of sensitivity is uncertain. Individual animals vary considerably in the degree of hypersensitivity manifested to brucellin. Animals in the very early stages of infection, or with long-standing infection, may not manifest hypersensitivity to intradermal injection.

2.2.3.5. Stability

The freeze-dried preparation retains full potency for several years. The liquid commercial preparation should retain potency for the recommended shelf-life.

7 An EU reference brucellin (2000 Units/ml) is obtainable from the WOAH Reference Laboratory for Brucellosis in France.
8 The statistical procedure can be obtained from the WOAH Reference Laboratory for Brucellosis in France.

CHAPTER 3.1.5.

CRIMEAN–CONGO HAEMORRHAGIC FEVER

SUMMARY

Crimean–Congo haemorrhagic fever virus (*CCHFV*) *of the genus* Orthonairovirus *of the family* Nairoviridae *causes a zoonotic disease in many countries of Asia, Africa, the Middle East and south-eastern Europe. As the distribution of CCHFV coincides with the distribution of its main vector, ticks of the genus* Hyalomma*, the spread of infected ticks into new, unaffected areas facilitates the spread of the virus. The virus circulates in a tick–vertebrate–tick cycle, but can also be transmitted horizontally and vertically within the tick population.* Hyalomma *ticks infest a wide spectrum of different wildlife species, e.g. deer and hares, and free-ranging livestock animals, e.g. goat, cattle, and sheep. Many birds are resistant to infection, but ostriches appear to be more susceptible. Viraemia in livestock is short-lived, and of low intensity. These animals play a crucial role in the life cycle of ticks, and in the transmission and amplification of the virus and are, therefore, in the focus of veterinary public health. As animals do not develop clinical signs, CCHFV infections have no effect on the economic burden regarding livestock animal production. In contrast to animals, infections of humans can result in the development of a severe disease, Crimean–Congo haemorrhagic fever* (*CCHF*).

Every year, more than 1000 human CCHF cases are reported with case fatality rates of 5–80% depending on the virus strain and other local factors. The pathogenesis of the disease in humans is not well understood. Most people become infected by tick bites and by crushing infected ticks, but infection is also possible through contact with blood and other body fluids of viraemic animals, for example in slaughterhouses. As CCHFV also has the potential to be transmitted directly from human-to-human, nosocomial outbreaks have been reported.

There is no approved CCHF vaccine available and therapy is restricted to treatment of the symptoms. Health education and information on prevention and behavioural measures are most important in order to enhance public risk perception and, therefore, decrease the probability of infections. Thus the identification of endemic areas is crucial for focused and targeted implementation of public health measures. Serological screening of ruminants allows CCHFV-affected areas to be identified, as antibody prevalence in animals is a good indicator of local virus circulation. Treatment with tick repellents can be quite effective in reducing the tick infestation of animals. To protect laboratory staff, handling of CCHFV infectious materials should only be carried out at an appropriate biocontainment level.

Detection and identification of agent: *Only a single virus serotype is known to date although sequencing analysis indicates considerable genetic diversity. CCHFV has morphological and physiochemical properties typical of the family* Nairoviridae*. The virus has a single-stranded, negative-sense RNA genome consisting of three segments: L* (*large*)*, M* (*medium*) *and S* (*small*)*, each of which is contained in a separate nucleocapsid within the virion. The virus can be isolated from serum or plasma samples collected during the febrile or viraemic stage of infection, or from liver of infected animals. Primary isolations are made by inoculation of several tissue cultures, commonly African green monkey kidney* (*Vero*) *cells. For identification and characterisation of the virus, conventional and real-time reverse transcription polymerase chain reaction* (*PCR*) *can be used. As infections of animals remain clinically unapparent, the likelihood of isolating virus from a viraemic animal is very low.*

Serological tests: *Type-specific antibodies are demonstrable by indirect immunofluorescence test or by IgG-sandwich and IgM-capture enzyme-linked immunosorbent assay. Commercial test systems are available for animal health; in addition a few in-house systems have been published or kits are used replacing the conjugate provided in kit with one that is suitable for the animal species to be screened for CCHFV-specific antibodies.*

Requirements for vaccines: *There is no vaccine available for animals.*

A. INTRODUCTION

Crimean-Congo haemorrhagic fever (CCHF) is a zoonotic disease caused by a primarily tick-borne CCHF virus (CCHFV) of the genus *Orthonairovirus* of the family *Nairoviridae,* order *Bunyavirales*. CCHFV possesses a negative-sense RNA genome consisting of three segments, L (large), M (medium) and S (small) each contained in a separate nucleocapsid within the virion. All orthonairoviruses are believed to be transmitted by either ixodid or argasid ticks, and only three are known to be pathogenic to humans, namely CCHF, Dugbe and Nairobi sheep disease viruses (Swanepoel & Burt, 2004; Swanepoel & Paweska, 2011; Whitehouse, 2004). CCHFV can be grown in several tick cell lines derived from both a natural vector (*Hyalomma anatolicum*) and other tick species not implicated in natural transmission of the virus (Bell-Sakyi*et al*., 2012).

The virus from an outbreak of "Crimean haemorrhagic fever" in the Crimean Peninsula in 1944 was not isolated or characterised until 1967. "Congo haemorrhagic fever" virus, isolated from a patient in the former Zaire (now Democratic Republic of the Congo) in 1956, was shown in 1969 to be the same virus. As a consequence the names of both countries have been used in combination to describe the disease (Hoogstraal, 1979). Distribution of the virus reflects the broad distribution of *Hyalomma* ticks, the predominant vector of the virus (Avsic-Zupanc, 2007; Grard *et al*., 2011; Papa *et al*., 2011; Swanepoel & Paweska, 2011).

The natural cycle of CCHFV includes transovarial and transstadial transmission among ticks and a tick-vertebrate-tick cycle involving a variety of wild and domestic animals. Infection can also be transferred between infected and uninfected ticks during co-feeding on a host; so called 'non-viraemic transmission' phenomenon. *Hyalomma* ticks feed on a variety of domestic ruminants (sheep, goats, and cattle), and wild herbivores, hares, hedgehogs, and certain rodents. CCHFV infection in animals was reviewed by Nalca & Whitehouse (2007). Experimental infections of wild animals and livestock with CCHFV were reviewed by Spengler *et al. (*2016). Although animal infections are generally subclinical, the associated viraemia levels are sufficient to enable virus transmission to uninfected ticks (Swanepoel & Burt, 2004; Swanepoel & Paweska, 2011). Many birds are resistant to infection, but ostriches appear to be more susceptible than other bird species (Swanepoel *et al*., 1998). Although they do not appear to become viraemic, ground feeding birds may act as a vehicle for spread of CCHFV infected ticks. Results from serological surveys conducted in Africa and Eurasia indicate extensive circulation of the virus in livestock and wild vertebrates (Swanepoel & Burt, 2004).

Humans acquire infection from tick bites, or from contact with infected blood or tissues from livestock or human patients. After incubation humans can develop a severe disease with a prehaemorrhagic phase, a haemorrhagic phase, and a convalescence period. Haemorrhagic manifestations can range from petechiae to large haematomas. Bleeding can be observed in the nose, gastrointestinal system, uterus and urinary tract, and the respiratory tract, with a case fatality rate ranging from 5% to 80% (Ergonul, 2006; Yen *et al.,* 1985; Yilmaz *et al*., 2008).The severity of CCHF in humans highlights the impact of this zoonotic disease on public health. Although CCHFV has no economic impact on livestock animal production, the serological screening of animal serum samples for CCHFV-specific antibodies is very important. As seroprevalence in animals is a good indicator for local virus circulation, such investigations allow identification of high-risk areas for human infection (Mertens *et al.,* 2013). Slaughterhouse workers, veterinarians, stockmen and others involved with the livestock industry should be made aware of the disease. They should take practical steps to limit or avoid exposure of naked skin to fresh blood and other animal tissues, and to avoid tick bites and handling ticks. Experiences from South Africa demonstrated that the use of repellents on animals before slaughter could reduce the numbers of infected slaughterhouse workers (Swanepoel *et al.,* 1998). The treatment of livestock in general can reduce the tick density among these animals and thus reduce the risk of tick bite in animal handlers (Mertens *et al.,* 2013). Such tick control by the use of acaricides is possible to some extent, but may be difficult to implement under extensive farming conditions. Inactivated mouse brain vaccine for the prevention of human infection has been used on a limited scale in Eastern Europe and the former USSR (Swanepoel & Paweska, 2011). Progress in CCHFV vaccine development is being made with several different approaches trialled to overcome current challenges (Dowall *et al.,* 2017).

Infectivity of CCHFV is destroyed by boiling or autoclaving and low concentrations of formalin or beta-propriolactone. The virus is sensitive to lipid solvents. It is labile in infected tissues after death, presumably due to a fall in pH, but infectivity is retained for a few days at ambient temperature in serum, and for up to 3 weeks at 4°C. Infectivity is stable at temperatures below –60°C (Swanepoel & Paweska, 2011). CCHFV should be handled with appropriate biocontainment measures determined by risk analysis as described in Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities* (Palmer, 2011; Whitehouse, 2004).

B. DIAGNOSTIC TECHNIQUES

Table 1. Diagnostic test formats for Crimean-Congo haemorrhagic fever virus infections in animals

Method	Purpose					
	Population freedom from infection	Individual animal freedom from infection prior to movement	Contribute to eradication policies	Confirmation of clinical cases in animals	Prevalence of infection – surveillance	Immune status in individual animals or populations post-vaccination
Detection and identification of the agent[a]						
Real-time RT-PCR	–	+++	–	+++[c]	+[b]	–
Virus isolation in cell culture	–	–	–	+[c]	–	–
Detection of immune response						
IgG ELISA	+++	+	–	+	+++	–
Competitive ELISA	+++	+	–	+	+++	–
IgM ELISA	–	++	–	++	–	–

Key: +++ = recommended for this purpose; ++ recommended but has limitations;
+ = suitable in very limited circumstances; – = not appropriate for this purpose.
RT-PCR = reverse-transcription polymerase chain reaction; ELISA = enzyme-linked immunosorbent assay.
[a]A combination of agent identification methods applied on the same clinical sample is recommended.
[b]RT-PCR is used for the screening of tick populations in the context of surveillance studies.
[c]Molecular testing/isolation can be used to confirm acute infection in rare cases in animals showing clinical signs as viraemia tends to be transient.

CCHFV infection causes only a mild fever in domestic and wild vertebrate animals with a detectable viraemia of up to 2 weeks (Gonzalez *et al.,* 1998; Gunes *et al.,* 2011). Similarly infected ostriches develop only low and short-lived viraemia and no clinical signs (Swanepoel & Burt, 2004). Therefore, recent infections in animals are rarely diagnosed and methods such as polymerase chain reaction (PCR), virus isolation in cell culture and IgM detection by enzyme-linked immunosorbent assay (ELISA) are mainly used in human CCHF diagnostics or in the special case that an animal has to be classified as CCHFV free. For prevalence analysis and for determination of whether CCHFV is circulating in a country, methods for the detection of IgG antibodies are preferred (Table 1). If there is any possibility or suspicion that diagnostic samples could be contaminated with CCHFV, they should be handled under an adequate biosafety level and all persons dealing with those samples should be aware of the possible risk and should use personal protective equipment to avoid human infections.

1. Detection and identification of the agent

For testing animals for viraemia, rapid diagnosis can be achieved by detection of viral nucleic acid in serum or plasma using conventional (Burt *et al.,* 1998) or real-time reverse transcription (RT-) PCR (Drosten *et al.,* 2002; Duh *et al.,* 2006; Koehler *et al.*, 2018; Negredo *et al.*, 2017; Sas *et al.*, 2018; Wolfel *et al.,* 2007), or by demonstration of viral antigen (Shepherd *et al.,* 1988). Specimens to be submitted for laboratory confirmation of CCHF include blood and liver samples. Because of the risk of laboratory-acquired infections, work with CCHFV should be conducted in appropriate biosafety facilities.

The virus can be isolated from serum and organ suspensions in a wide variety of cell cultures, including Vero, LLC-MK2, SW-13, BSR-T7/5, CER and BHK21 cells, and identified by immunofluorescence using specific antibodies. Isolation and identification of virus can be achieved in 1–5 days, but cell cultures lack sensitivity and usually only detect high concentrations of virus present in the blood.

1.1. Virus isolation in cell culture

CCHFV can be isolated in mammalian cell cultures. Vero cells are commonly used, usually yielding an isolate between 1 and 5 days post-inoculation (p.i). CCHFV is poorly cytopathic and thus infectivity is

titrated by demonstration of immunofluorescence in infected cells (Shepherd *et al*., 1986). SW-13 cell line has also been used extensively for virus isolation, producing plaques within 4 days (p.i.). Identification of a CCHFV isolate has to be confirmed by immunofluorescence or molecular techniques (Burt *et al*., 1998; Shepherd *et al*., 1986).

1.1.1. Test procedure

i) Susceptible cell lines include Vero-E6, BHK-21, LLC-MK2 and SW-13 cells. Inoculate 80% confluent monolayers of the preferred cell line with the specimen. The volume of specimen to be used depends on the size of the culture vessel (i.e. 25 cm^2 culture flask or 6- or 24-well tissue culture plate). The specimen volume should be sufficient to cover the cell monolayer. Samples of insufficient volumes can be diluted with tissue culture medium to prepare sufficient inoculation volume.

ii) Adsorb the specimen for 1 hour at 37°C.

iii) Remove inoculum. Add fresh tissue culture medium containing 2% fetal calf serum and other required additives, as per specific medium and cell line requirements.

iv) Incubate at 37°C and 5% CO_2 for 4–7 days.

v) Test supernatant for presence of CCHFV viral RNA using real-time RT-PCR as described below, or perform immunofluorescence assay on cell scrapings.

vi) Isolates of CCHFV from clinical specimens cause no microscopically recognisable cytopathic effects (CPE) in most of these cell lines.

1.2. Nucleic acid detection

Molecular-based diagnostic assays, such as RT-PCR, serve as the front-line tool in the diagnosis of CCHF, as well as other viral haemorrhagic fevers (Drosten *et al*., 2003). The benefit of molecular diagnostic assays is their rapidity compared to virus culture, often allowing a presumptive diagnosis to be reported within a few hours after receiving a specimen (Burt *et al*., 1998). The RT-PCR is a sensitive method for diagnosis, but because of the genetic diversity of CCHFV, there might be some challenges with regard to design of primers or probes that allow detection of all circulating strains of the virus. Indeed, based on geographical origin and phylogenetic analyses of the S gene segment, CCHFV has previously been classified into nine geographical clades – four predominantly diffused in Africa, three in Europe, and two in Asia. Several real-time RT-PCR assays that detect strains from different geographical locations have been evaluated (Gruber *et al.,* 2019). While some assays have been shown to be highly sensitive, detecting as little as 10 viral RNA copies per ml of plasma, it is necessary to combine at least two molecular assays to ensure detection of the different CCHFV clades (Gruber *et al.,* 2019). The best assay combination(s) with the best detection efficacy for each CCHFV clade, on the basis of all CCHFV sequences known at the time of the study, are shown in Table 2. In addition, a low-density macroarray has been extensively validated in clinical specimens collected from confirmed cases of CCHF over 20 years by a WHO reference laboratory. It was shown to detect as few as 6.3 genome copies per reaction (Wolfel *et al*., 2009).

(Data and table modified from Gruber *et al*. 2019)

2. Serological tests

Virus neutralisation assays, generally considered to be highly specific, are rarely used for CCHFV diagnosis. Members of the *Orthonairovirus* genus generally induce a weaker neutralising antibody response than members of other genera in the family *Nairoviridae.* Another drawback is the necessity to perform this assay in high biosafety containment because it uses live virus (Burt *et al*., 1994; Rodriguez *et al*., 1997).

Currently, there are only a few CCHFV commercial kits for IgM or IgG by ELISA or immunofluorescence (IFA). These are all designed for the human diagnostic market. However, it is possible to adapt these commercial ELISAs and IFAs for serological testing in animals. In addition, some in-house ELISAs have been published for the detection of CCHFV-specific antibodies in animals.

Diagnostic performance for humans have been compared between the methods using sensitivity, specificity, concordance and degree of agreement with particular focus on the phase of the infection (Emmerich *et al.,* 2021). Available serological test systems detect anti-CCHFV IgM and IgG antibodies accurately, but their diagnostic performance varies with respect to the phase of the infection. In the early and convalescent phases of infection, the sensitivity for detecting specific IgG antibodies differed for the ELISA. Both test systems based on immunofluorescence showed an identical sensitivity for detection of anti-CCHFV IgM antibodies in acute and convalescent phases of infection.

IgM antibodies in livestock (sheep, goat and cattle) can be detected by using an IgM-capture ELISA. IgG antibodies can be detected by an IgG-sandwich or indirect ELISA, and total antibodies can be detected by competition ELISA. The benefit of competitive ELISA is the capacity to investigate different animal species, because they are host species independent. Commercial kits for the detection of CCHFV-specific antibodies or the detection of viral antigen are available. The limiting factor for the replication of these protocols in other laboratories is the availability of antigens and (where relevant) specified monoclonal antibodies. Most of the tests described for livestock and wild animals have not undergone a formal validation process (Mertens *et al*., 2013). One of the biggest challenges for such validation studies is the availability of an adequate number of positive well characterised control samples.

For information on the availability of reference reagents for use in veterinary diagnostic laboratories, contact the WOAH Collaborating Centres for Zoonoses in Europe and in Asia-Pacific.

C. REQUIREMENTS FOR VACCINES

There is no vaccine available for animals.

CHAPTER 3.1.6.

ECHINOCOCCOSIS (INFECTION WITH *ECHINOCOCCUS GRANULOSUS* AND WITH *E. MULTILOCULARIS*)

SUMMARY

Human cystic echinococcosis, caused by Echinococcus granulosus sensu lato (s.l.)*, and alveolar echinococcosis, caused by* E. multilocularis*, are important public health threats in many parts of the world. Diagnosis of echinococcosis in dogs or other susceptible carnivores relies on the detection of adult cestodes of the* Echinococcus *genus or their eggs in the faeces or small intestine. Coproantigen and coproDNA assays have proven useful particularly for epidemiological screening programmes For the metacestode stage, diagnosis in humans is performed by imaging techniques supported by immunological tests, while in animals, diagnosis is based on post-mortem detection of the larval form that can infect almost any organ, particularly the liver and lungs, with subsequent species confirmation by polymerase chain reaction (PCR)* and DNA sequencing.

Detection of the agent: *It was previously accepted that there were five valid species of the genus* Echinococcus; *the current view however, informed by biology, epidemiology and particularly molecular genotyping, recommends the inclusion of at least nine species within the genus. All those species of* Echinococcus *known to cause cystic echinococcosis in the intermediate host may be referred to as* E. granulosus s.l.*, whereas genotypes G1,3 which are closely related are now referred to as* E. granulosus sensu stricto (s.s.)*. It is also widely believed that within* E. granulosus s.l., E. equinus (*G4*), E. ortleppi (*G5*) *and* E. canadensis (*G6, G7, G8, G10*) *should be considered as distinct species although there is still some debate as to whether* E. canadensis *represents more than one species. Larval forms of* E. granulosus s.l. *and* E. multilocularis *in intermediate hosts can be detected by macroscopic and microscopic examination of visceral organs. Special care has to be taken for a specific diagnosis of* E. granulosus *in instances where* Taenia hydatigena *in sheep is also a problem. Histological examination may confirm the diagnosis after formalin-fixed material is processed by conventional staining methods. The presence of a periodic-acid-Schiff positive, acellular laminated layer with or without an internal cellular, nucleated germinal membrane can be regarded as a specific characteristic of metacestodes of* Echinococcus*. Genotyping via PCR/sequencing is the only method available to confirm the exact species of* Echinococcus *infecting animals. The small intestine is required at necropsy for the detection of adult* Echinococcus *spp. in definitive hosts* (*wild and domestic carnivores*)*. Handling infected material needs detailed safety precautions to avoid risk to the operator of contracting a potentially fatal disease.*

Coproantigen or CoproDNA tests: *Significant progress is being made in the development of immunological tests for the diagnosis of intestinal* Echinococcus *infections by use of coproantigen detection. The technique has been used successfully only in some countries for surveys of* E. granulosus *in dogs and is currently used in surveys for* E. multilocularis *in populations of dogs and foxes in high endemic areas. Coproantigen detection is possible in faecal samples collected from dead or living animals or from the environment. However, as these tests were developed based on adult worm antigens, false positives may occur. PCR DNA methods for the detection of* E. multilocularis *and more recently* E. granulosus *in definitive hosts have now been validated as diagnostic techniques.*

Serological tests: *Antibodies directed against oncosphere, cyst fluid and protoscolex antigens can be detected in the serum of infected dogs and sheep, but this approach is presently of limited practical use as it does not distinguish between current and previous infections. Moreover, analytical*

sensitivity and specificity can sometimes be poor as cross-reactivity between Echinococcus *and* Taenia *species also may occur.*

Requirements for vaccines: *A vaccine for* E. granulosus *s.s. based on the EG95 recombinant antigen has proven to be safe and effective in livestock. Commercial EG95 vaccines are available and are manufactured in Argentina, Morocco and China (People's Rep. of). The vaccines have gained regulatory approval in the countries of manufacture as well as a number of other countries. The EG95 vaccine was adopted in 2016 as a compulsory part of the national program for control of echinococcosis in China. No vaccine is available for Echinococcus infection in the parasites' definitive hosts.*

A. INTRODUCTION

The species within the genus *Echinococcus* are small (1–11 mm length) tapeworms of carnivores with a larval stage known as metacestode that proliferates asexually encysting in the internal organs of various mammals including humans. Until recently it was accepted that there were five morphologically distinct species in this genus: *Echinococcus granulosus s.l.*, *Echinococcus multilocularis*, *Echinococcus oligarthra*, *Echinococcus vogeli* and *Echinococcus shiquicus*. However, the current view, informed by biology, epidemiology and particularly molecular genotyping, recommends the inclusion of at least nine species within the genus. *Echinococcus granulosus s.l.*, formerly regarded as a single species with a high genotypic and phenotypic diversity, is now recognised as an assemblage of five cryptic species, which differ considerably in morphology, development, host specificity (including infectivity or pathogenicity for humans). This diversity is reflected in the mitochondrial and nuclear genomes. Based on phenotypic characters and gene sequences, *E. granulosus s.l.* has now been subdivided into *E. granulosus sensu stricto* (*s.s.*) (including the formerly identified genotypic variants G1, 3), *Echinococcus felidis* (the former 'lion strain'), *Echinococcus equinus* (the 'horse strain', genotype G4), *Echinococcus ortleppi* (the'cattle strain', genotype G5) and *Echinococcus canadensis*. The latter species, as recognised here, shows the highest diversity and is composed of the 'camel strain', genotype G6, the 'pig strain', genotype G7, and two 'cervid strains', genotypes G8 and G10 (Nakao *et al*., 2013; Romig *et al*., 2015). Studies performed on nearly complete mitochondrial genome and significantly long nuclear genetic DNA sequences suggest the previous G2 genotype be considered a microvariant of G3 (Kinkar *et al*., 2017) and *E. canadensis* be considered a cluster composed of two different species (Laurimae *et al.,* 2018).

Echinococcus granulosus (s.l.) has a global distribution; *E. multilocularis* occurs in wide areas of the northern hemisphere, *E. shiquicus* is found in the Tibetan plateau and *E. oligarthra* and *E. vogeli* are confined to Central and South America. Nearly all the originally described species are infective to humans causing various echinococcal diseases, although in the most recent taxonomic classification there is no evidence of *E. shiquicus* and *E. felidis* infections in humans (Ma *et al*., 2015). Human cystic echinococcosis (CE), caused by *E. granulosus s.l.,* and alveolar echinococcosis (AE), caused by *E. multilocularis*, are important public health threats in many parts of the world (WHO/WOAH, 2001) caused by ingestion of eggs derived directly or indirectly from definitive hosts. The strong zoonotic potential of *E. granulosus s.l.* is mainly related to *E. granulosus s.s.* (Alvarez Rojas *et al.,* 2014). Clinical specimens and eggs of *Echinococcus* spp. should be handled with appropriate biosafety and containment procedures as determined by biorisk analysis (see Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*).

Table 1. Useful characteristics for identification of Echinococcus species (source: Xiao* et al.*, 2006)

	***E. granulosus* (*sensu lato*)**	***E. multilocularis***	***E. oligarthra***	***E. vogeli***	***E. shiquicus***
Distribution	Cosmopolitan	Holoarctic region	Neotropical region	Neotropical region	Tibet plateau
Definitive host	Wild and domestic carnivores	Foxes/dogs	Wild felids	Bush dog	Tibetan fox
Intermediate host	Ungulates	Microtine rodents	Neotropical rodents	Neotropical rodents	Plateau pika

	E. granulosus (*sensu lato*)	*E. multilocularis*	*E. oligarthra*	*E. vogeli*	*E. shiquicus*
Adult					
Body length (mm)	2.0–11.0	1.2–4.5	2.2–2.9	3.9–5.5	1.3–1.7

Length of large hooks (μm)	25.0–49.0	24.9–34.0	43.0–60.0	49.0–57.0	20.0–23.0
Length of small hooks (μm)	17.0–31.0	20.4–31.0	28.0–45.0	30.0–47.0	16.0–17.0
No. testes	25–80	16–35	15–46	50–67	12–20
Position of genital pore					
a. Mature segment	Near to middle	Anterior to middle	Anterior to middle	Posterior to middle	Near to upper edge
b. Gravid segment	Posterior to middle	Anterior to middle	Near to middle	Posterior to middle	Anterior to middle
Gravid uterus	Branching laterally	Sac-like	Sac-like	Tubular	Sac-like
Metacestode	Unilocular cysts in viscera	Multilocular cysts in viscera	Unicystic cysts in muscles	Polycystic cysts in viscera	Unilocular cysts in viscera

1. *Echinococcus granulosus sensu lato* (*s.l.*)

The parasite is most frequently transmitted between the domestic dog and a number of domestic ungulate species. In countries where sheep farming plays an important role in the local economy, *E. granulosus s.s.* is maintained prevalently by a dog–sheep cycle. Sylvatic cycles involving different definitive and intermediate hosts (e.g. wolf or cervid) have been reported for *E. canadensis* (see Deplazes *et al.,* 2017 for further illustration) and for *E. felidis,* with lion or spotted hyena acting as definitive hosts. There is some intermediate host predilection in some strains – e.g. *E. equinus* in horses, *E. ortleppi* in cattle and *E. canadensis* in pigs, camels and cervids. The adult worm varies between 2 and 11 mm in length and usually possesses from two to seven segments, averaging from three to four segments. The penultimate segment is mature, and the genital pore normally opens posterior to the middle in both mature and gravid segments. The last (gravid) segment is usually more than half the length of the entire worm. There are rostellar hooks of various sizes on the protoscolex in two rows. The size of the hooks varies between 25 and 49 μm in the first row, and between 17 and 31 μm in the second row. The gravid uterus has well-developed sacculations.

The metacestode, known as hydatid, is a fluid-filled bladder that is typically unilocular, although communicating chambers may also occur. Growth is expansive, and newly formed hydatids (daughter cysts) inside and, occasionally, outside the cyst may be produced. Individual CE cyst may reach up to 30 cm in diameter and occur mainly in liver and lungs. Other internal organs are affected less frequently. The infection with this stage is referred to as cystic echinococcosis

2. *Echinococcus multilocularis*

The parasite is transmitted primarily between wild definitive hosts (e.g. foxes, *Vulpes vulpes, V. corsac*, *Alopex lagopus*) and small arvicolid rodents (voles and lemmings). The adult varies between 1.2 and 4.5 mm in length and usually possesses from two to six segments, with an average of four to five. The penultimate segment is characteristically mature, and the genital pore is anterior to the midline in both mature and gravid segments. The gravid uterus is sac-like. On the rostellum, the larger hooks of the first row vary in size between 24.9 and 34.0 μm and the smaller hooks of the inner row between 20.4 and 31.0 μm.

The metacestode is a multivesicular structure consisting of conglomerates of small vesicles, usually not exceeding a few millimetres in diameter. Unlike *E. granulosus*, the larval mass often contains a semisolid rather than a fluid matrix. It proliferates by exogenous budding, which results in infiltration of tissues. Infection with this stage is commonly referred to as alveolar echinococcosis.

This zoonotic parasite is found mainly in the Northern Hemisphere, and its life cycle is mainly maintained in wildlife (Deplazes *et al.,* 2017). Like *E. granulosus,* there are a number of genetic variants or haplotypes based on microsatellite EmsB and mitochondrial gene sequences. These are associated with different geographical regions and have been named the Asian, the Mongolian, the North American 1, the North American 2 and the European haplotypes. In Europe the prevalence of *E. multilocularis* in red foxes varied from zero to >10% in different countries, and over 50% in high endemic areas. *E. multilocularis* has also been detected in Arctic foxes (Deplazes *et al.,* 2017). Domestic dogs, raccoon dogs, golden jackals and wolves have also been shown to act as definitive hosts. Experimental studies indicate that domestic cats play an insignificant role in transmission (Kapel *et al.,* 2006). Rodents of the genus *Microtus, Arvicola, Myodes* and *Lemmus* are all known to be suitable intermediate hosts as are muskrats (*Ondatra zibethicus*), nutria/coypu (*Myocastor coypus*) and beaver (*Castor fiber*).

3. *Echinococcus oligarthra*

The parasite typically uses neotropical wild felids as definitive hosts (e.g. *Felis concolor, F. jaguarundi*) and large rodents (e.g. *Dasyprocta* sp., *Cuniculus paca*) as intermediate hosts. The adult varies between 2.2 and 2.9 mm in length, and normally possesses three segments, the penultimate of which is mature. The genital pore is anterior to the middle in mature segments and approximately at the middle in gravid segments. The gravid uterus is sac-like.

The metacestode is polycystic and fluid-filled with a tendency to become septate and multichambered. The rostellar hooks of the protoscolex vary in length between 25.9 and 37.9 μm. The hooks are described in more detail in the next section where they are also compared with those of *E. vogeli*. The single cyst may reach a diameter of approximately 5 cm. Predilection sites are internal organs and muscles. To date, there have only been a few reports of human disease. The parasite appears not to mature in dogs.

4. *Echinococcus vogeli*

The parasite typically uses the South American bush dog (*Speothus venaticus*) as a wild definitive host, but the domestic dog is susceptible, as are large rodents (e.g. *Cuniculus paca*) as intermediate hosts. The adult varies between 3.9 and 5.5 mm in length, and usually has three segments, the penultimate of which is mature. The genital pore is situated posterior to the middle in both the mature and gravid segments. The gravid uterus has no lateral sacculations and is characterised by being relatively long and tubular in form, compared with the other segments, which are sac-like.

The metacestode is similar to that of *E. oligarthra*. It has been reported that the two species can be distinguished by comparing differences in the dimensions and proportions of the rostellar hooks on the protoscolex. The hooks of *E. oligarthra* vary in length between 25.9 and 37.9 μm (average 33.4 μm) and between 22.6 and 29.5 μm (average 25.45 μm) for large and small hooks, respectively. Those of *E. vogeli* vary between 19.1 and 43.9 μm (average 41.64 μm) and between 30.4 and 36.5 μm (average 33.6 μm) for the large and small hooks, respectively. The hook-guard for *E. oligarthra* also divides the hook 50:50, compared with 30:70 for *E. vogeli.*

Echinococcus vogeli is a zoonotic agent with approximately 200 human cases in total reported in South America. The infection caused by the larval stage of this species may be referred to as neotropical echinococcosis.

5. *Echinococcus shiquicus*

The parasite was found in the Tibetan fox (*Vulpes ferrilata*) its definitive host and the plateau pika (*Ochotona curzoniae*), the intermediate host. In most species of *Echinococcus*, the gravid segment is connected to a mature segment; however, a strobila consisting of only two segments (a gravid segment directly attaching to a premature segment) is unique to this species (Xiao *et al.,* 2005). The adult stage is morphologically similar to *E. multilocularis* but differs by its smaller hooks, fewer segments, upper position of genital pore in the premature segment and fewer eggs in the gravid segment. It is easily distinguishable from *E. granulosus* by its shorter length, branchless gravid uterus and the anterior position of the genital pore in the gravid segment. The adult measures 1.3 to 1.7 mm.

The metacestode is found mainly in the lungs of pika and is essentially a unilocular minicyst containing fully developed brood capsules; however, oligovesicular forms have also been observed. It is differentiated from *E. granulosus* by the absence of daughter cysts within the fertile cyst (WHO/WOAH, 2001).

A detailed description of echinococcosis in humans and animals can be found in the WHO/WOAH Manual on echinococcosis (WHO/WOAH, 2001).

B. DIAGNOSTIC TECHNIQUES

Table 2. Test methods available for the diagnosis of echinococcosis and their purpose

Method	Purpose (metacestode cysts in intermediate hosts)					
	Population freedom from infection	Individual animal freedom from infection prior to movement	Contribute to eradication policies	Confirmation of clinical cases[(a)]	Prevalence of infection – surveillance	Immune status in individual animals or populations post-vaccination
Detection and identification of the agent						
Parasite Identification /meat inspection	++	–	++	++	++	–
Antigen detection	–	–	–	–	–	–
PCR	++	–	–	+++	++	–
Detection of immune response						
ELISA	–	–	–	–	+	+
Purpose (adult worms in carnivorous definitive hosts)						
Detection of the agent						
Parasite isolation/ microscopy	+	+	+++	+++	++	–
Antigen detection	+	++	+++	+++	++	–
PCR	–	++	+++	+++	+++	–
Detection of immune response						
ELISA	–	–	–	–	+	–

Key: +++ = recommended for this purpose; ++ recommended but has limitations;
+ = suitable in very limited circumstances; – = not appropriate for this purpose.
PCR = polymerase chain reaction; ELISA = enzyme-linked immunosorbent assay.
[(a)]Meat inspection may only identify cysts seen and not include subsequent tests to confirm they are due to *Echinococcus granulosus* infection.

1. Detection of the agent

In the intermediate host, diagnosis depends on the meat inspection or post-mortem detection of the larval cyst form, which can occur in almost any organ, particularly in the liver and lungs. The diagnosis of echinococcosis in dogs or other carnivores requires the demonstration of the adult cestodes of *Echinococcus* spp. in the small intestine or the detection of specific coproantigens or coproDNA in faeces. Comprehensive reviews are available

relating to diagnostic procedures for *E. granulosus s.l.* (Craig *et al.,* 2015) and *E. multilocularis* (Conraths & Deplazes, 2015).

Investigators carrying out these procedures are exposed to the risk of infection and severe disease, which must be minimised by appropriate biosafety and containment procedures as determined by biorisk analysis (see Chapter 1.1.4). Infective (egg/adult) material can be decontaminated by freezing at –80°C (core temperature) for 5 days, or by heating to 70°C for 1 hour. Face masks, disposable gloves and an apron must be worn. Chemical disinfection is not reliable, although sodium hypochlorite (10% bleach) can be used to destroy eggs. Contaminated material must be destroyed by incineration or autoclaving.

1.1. Diagnosis of larval echinococcosis in intermediate hosts

1.1.1. Necropsy

Whereas surveillance for *E. granulosus s.l.* in domestic animals may take place in licensed slaughter houses, that for *Echinococcus* spp. in wildlife must be done by field surveys. When undertaking surveillance work with *E. granulosus s.l.* in intermediate hosts, it is vitally important that data are stratified and reported according to the age of animals slaughtered. Prevalence rates are strongly age dependent and reports from abattoirs that may slaughter only young animals will substantially under-represent the true situation. This is because older animals may be heavily infected even when animals have very few larvae.

CE cysts can be observed in many organs, but in large animals, such as sheep and cattle, palpation or incision should be done. Pigs, cattle, sheep and goats may also be infected with larval *Taenia hydatigena,* and it is sometimes difficult to differentiate between these two parasites when they occur in the liver. In wild animals, such as ruminants and rodents, several other larval cestodes should be considered for differential diagnosis. Please refer to Chapter 3.9.5 *Cysticercosis* for information on other cestodes found at meat inspection.

i) Suspect parasite material should be removed from the organ by cutting with a scalpel to include the immediate host tissue, and kept in a cool location. (**NB**: parasite material in intact cysts will remain viable for more than 24 hours after death even at ambient temperatures. However viability will be prolonged by storage at 4°C for up to 72 hours. If material cannot be examined within this time, it should be stored either in 10% formol saline for subsequent microscopic examination or in 70–90% ethanol for subsequent DNA analysis. Ideally a sample of parasite material should be preserved in both media. Parasite tissues that are frozen will not be viable but can be examined morphologically on thawing and subjected to DNA analyses.

ii) For morphological analysis of cyst contents, fluid should be removed and retained using a syringe. The material inside the cyst should then be washed with saline and the contents examined under the microscope (×4 objective) for the presence of protoscoleces. Note that some CE cysts may be sterile and not contain protoscoleces. If no protoscoleces are present, the germinal layer on the inside of the cyst cavity may be observed as a gelatinous structure that can easily be pulled away. Formalin-fixed material can be stained by conventional histological techniques. The presence of a periodic-acid-Schiff (PAS) positive acellular laminated layer, underlying a connective tissue layer, and with or without an internal cellular, nucleated germinal membrane can be regarded as a specific characteristic of the metacestodes of *Echinococcus* spp.

iii) In all cases exact species/genotype identification can only be made through extraction of DNA from ethanol-fixed or frozen material and subsequent genotyping by polymerase chain reaction (PCR) and, where needed, sequencing. This requires either protoscoleces or pieces of germinal layer to be present. Cysts removed from animals should be cut open after the fluid has been removed and pieces of cyst wall removed to 70% ethanol. It is important to remember that identification of the parasite genotype can give significant information on transmission cycles and that an individual animal may contain mixed infections of more than one genotype. Specific primers based on mitochondrial genes (cox 1, NAD1) and ribosomal genes (12s) have been identified for all *Echinococcus* species and related taeniids and are summarised by Roelfsema *et al*. (2016). These also include primers listed for the detection of adult worms in Table 3, Section B.2.2.1.

1.2. Diagnosis of adult parasites in carnivores

1.2.1. Necropsy

Necropsy is invariably employed in studies of echinococcosis in wildlife and is useful if domestic carnivores are humanely culled. It should be emphasised that it is necessary to isolate and identify the adult *Echinococcus*, because under normal conditions of faecal examination, the eggs of *Echinococcus* cannot be differentiated from those of *Taenia* spp. The eggs of *E. granulosus* and *E. multilocularis* can now be identified and differentiated from other taeniid eggs by PCR. It should also be emphasised that any possible contact with eggs is potentially very hazardous and requires risk management. Tissues should be deep frozen at between –70°C and –80°C for 3–7 days before necropsy to kill any eggs.

The small intestine is removed as soon as possible after death, and tied at both ends. If the material is not frozen or formalin fixed (4–10%), it should be examined quickly, as the parasite can be digested within 24 hours. Formalin does not kill eggs. The fresh intestine is divided into several sections and immersed in 0.9% saline at 38±1°C for examination. Worms adhering to the intestinal wall may be observed and counted by means of a hand lens (for *E. granulosus* and *E. vogeli*). For accurate counts, the unfixed intestine is best divided into four or six sections, opened up and immersed in 0.9% saline at 38±1°C for 30 minutes to release the parasites. The contents are washed into another container for detailed examination, and the intestinal wall is scraped with a spatula. All material is boiled and washed by sieving to eliminate most of the particulate material and to make it non-infectious. The washed intestinal contents and scrapings are placed on a black tray, and the worms are counted with the aid of a hand lens or stereoscopic microscope. *E. granulosus* is usually found in the first third of the small intestine of dogs and *E. multilocularis* in the mid/posterior sections. This approach has a greater than 95% sensitivity, except under low worm burdens where false negative results may occur.

Necropsy is considered to be the most reliable form of diagnosis for *E. multilocularis* in definitive hosts. It is a useful method for determining the prevalence in a population and the best way to determine worm burden. Carcasses or intestines of definitive hosts for examination should be deep frozen at between –70°C and –80°C for 3–7 days before necropsy to kill any eggs. Eggs of *E. multilocularis* are resistant to freezing to –50°C. *Echinococcus multilocularis* can survive in liquid nitrogen (around –200°C) for 35 years and still be infective.

1.2.2. Sedimentation and counting technique (SCT) (Eckert, 2003)

This well established technique has been widely used, but is less sensitive than the coproDNA (PCR) test.

i) The small intestine is incised longitudinally and cut into 20 cm long segments or into five pieces of approximately the same length. These pieces are transferred to a glass bottle containing 1 litre physiological saline (0.9% NaCl) solution.

ii) The glass bottle is shaken vigorously for a few seconds and the pieces of intestine are removed. The superficial mucosal layer is stripped by exerting pressure between thumb and forefinger to dislodge attached helminths.

iii) The glass bottle is left for 15 minutes for sedimentation to occur; the supernatant is then decanted. The glass bottle is refilled with physiological saline solution. This procedure is repeated 2–6 times until the supernatant is cleared of coloured particles.

iv) The sediment fraction is examined in small portions of about 5–10 ml in rectangular plastic or Petri dishes with a counting grid (9× 9 cm) in transmission light under a stereomicroscope at a magnification of ×120.

v) If up to 100 worms are found, the entire sediment fraction is checked; if higher numbers are present, the total worm burden is calculated from the count of one subsample.

1.2.3. Preserving specimens

Intact worms are fragile and for morphological studies are best handled in normal saline with a Pasteur pipette. They are washed free of other material and left for approximately 30 minutes for all movement to cease. For all DNA characterisation, worms should be transferred to 70–90%

ethanol. For morphological studies, the worms should be fixed in 5–10% formalin. Persons involved in such examinations should receive serological screening for anti-*Echinococcus* serum-antibodies at least once a year (WHO/WOAH, 2001).

Methods have been developed aimed at simplifying and improving epidemiological investigations in final host populations and allowing diagnosis in living animals. These methods include the detection of coproantigens and PCR DNA detection (see below).

1.3. Arecoline surveys and surveillance

Purgation with arecoline has been used to perform surveys of tapeworm infections in dog populations. Its use as a control agent has been superseded by praziquantel. Arecoline can cause discomfort to dogs and its use for diagnostics is not recommended.

2. Coprological tests

Adult *Echinococcus* worms inhabiting the intestine will release both surface or secretory molecules (antigens) and DNA (usually contained within eggs). Both types of molecules can be detected by assaying faecal samples. The sensitivity of the tests is strongly influenced by the worm burden and stage of maturity.

2.1. Coproantigen tests

Coproantigen ELISA (enzyme-linked immunosorbent assay) or coproELISA provides an alternative method for diagnosing canine echinococcosis, and both polyclonal and monoclonal antibodies have been used, directed against either somatic or excretory/secretory (ES) antigens. To date, only a few commercial coproELISAs have been reported. Wang *et al.* (2021) evaluated these tests and found that they have good sensitivity and specificity. However, the kits are not easily available. Moreover, several tests developed within individual research laboratories, have been described even if, a certain amount of variability between tests from different laboratories regarding sensitivity and specificity are reported.

CoproELISAs are usually genus-specific for *Echinococcus* spp. (Allan & Craig, 2006). For canine echinococcosis due to *E. granulosus* most authors report reasonable sensitivity (78–100%) and good genus specificity from 85% to greater than 95% as well as a degree of pre-patent detection (Deplazes *et al*., 1992). Where cross-reactions occur these generally appear to be caused by infection with *Taenia hydatigena*, the most common taeniid of dogs, and attempts to improve specificity by using monoclonal antibodies in coproELISAs have not been able to eliminate this problem. CoproELISA sensitivity broadly correlates with worm burden of *E. granulosus*, however some low intensity infections (worm burdens <50–100) may give false negatives in coproELISA (Allan & Craig, 2006).

For detection of *E. multilocularis* infection of foxes, necropsy is time-consuming. Coproantigen testing by ELISA may offer a specific practical alternative. Fox faecal samples should be taken at post-mortem from the rectum rather than from the small intestine. *Echinococcus* coproantigens are also stable in fox or dog faeces left at 18–25°C for 1 week and in dog faeces frozen at –20°C. Coproantigen testing has also been successfully used to evaluate the efficacy of deworming wild foxes infected with *E. multilocularis* using praziquantel-laced bait, which proved to be a successful combination of eliminating the source of infection.

2.1.1. Typical coproantigen test procedure (*Echinococcus* genus specific) (Craig *et al.,* 1996)

i) The faecal sample (collected per rectum or from the ground) is mixed with an equal volume of phosphate buffered saline (PBS), pH 7.2, containing 0.3% Tween 20 (PBST), in a capped 5 ml disposable tube. This is shaken vigorously and centrifuged at 2000 ***g*** for 20 minutes at room temperature. Faecal supernatants can be tested immediately or stored at –20°C or lower. Supernatants that appear very dark or viscous are still acceptable for use.

ii) A 96-well ELISA microtitre plate is coated with optimal concentration (typically 5 µg per ml) of a protein A purified IgG fraction of rabbit anti-*E. granulosus s.l.* proglottid extract in 0.05 M bicarbonate/carbonate buffer, pH 9.6 (100 µl per well). The plate is covered and incubated overnight at 4°C.

iii) The wells are rinsed three times in PBST with 1 minute between washes; 100 µl of the same buffer is added to each well, and the plate is incubated for 1 hour at room temperature.

iv) The PBST is discarded and 50 µl of neat fetal calf serum is added to all wells. This is followed by the addition of 50 µl per well of faecal sample supernatants is added (in duplicate wells). The plate is incubated at room temperature for 1 hour with plastic film to seal the plate.

v) The wells are rinsed as in step iii, but the contents are discarded into a 10% bleach (hypochlorite) solution.

vi) An optimal dilution concentration of around 1 µg/ml of an IgG rabbit anti-*E.-granulosus* proglottid extract peroxidase conjugate in PBST is prepared and 100 µl per well is added to all wells. The plate is incubated for 1 hour at room temperature (22–24°C).

vii) The wells are rinsed as in step iii.

viii) Next, 100 µl per well of tetramethyl benzidene (TMB) or similar peroxidase substrate is added and the plate is left in the dark for 20 minutes at room temperature (22–24°C).

ix) Absorbance of wells is read at 650 nm. The enzyme-substrate reaction can be stopped by adding 100 µl of 1 M phosphoric acid (H_3PO_4) to each well. The colour turns from blue to yellow if positive and is read at 450 nm.

x) Laboratories should establish their own end-point criteria using standard positive and negative samples. Standards can also be obtained from the WOAH Reference Laboratory[1]. Usually, the positive to negative threshold is taken as 3 standard deviations above the mean absorbance value of control negatives, or against a reference standard control positive using absorbance units equivalence.

2.2. CoproDNA methods

2.2.1. Definitive hosts

While coproantigen ELISAs provide a better overall and practical alternative to arecoline purgation for pre-mortem detection of canine echinococcosis, their lack of species specificity is a disadvantage, especially for epidemiological studies. The amplification of small fragments of species-specific *Echinococcus* DNA in eggs or in faeces by PCR was first reported for *E. multilocularis* infections in foxes, with reduced inhibition and sensitivity subsequently increased by egg concentration through sieving and zinc chloride flotation of faecal samples (Mathis *et al*., 1996). Cabrera *et al.* (2002) applied this approach targeted to the mitochondrial cytochrome c oxidase subunit 1 (cox1) gene of *E. granulosus* as proof of principle for PCR identification of eggs of *E. granulosus* (with an analytic sensitivity of four eggs) isolated from adult tapeworms and faecal samples from necropsied dogs in Argentina. The ability to perform PCR with faecal samples or extracts directly without first isolating taeniid eggs is an advantage, especially when relatively large numbers of samples require testing. However faecal material preserved in formol saline is not suitable for DNA amplification and 70% ethanol or freezing should be used. Commercial extraction kits designed for faecal specimens can be used to extract total DNA from canid faecal samples (1–2 g). This approach has been used with at least two coproPCRs based on the EgG1 Hae III repeat (Abbasi *et al.,* 2003) and the NADH dehydrogenase subunit 1 gene (ND1) (Boufana *et al.,* 2013).

In recent years there have been a number of key developments attempting to simplify DNA amplification (e.g. loop-mediated isothermal amplification [LAMP]) (Ni *et al*., 2014; Salant *et al*., 2012) and improve sensitivity and specificity (e.g. real-time PCR) (Dinkel *et al.,* 2011; Knapp *et al.,* 2014; Øines *et al.,* 2014). This is important in relation to differential diagnosis between *E. granulosus* genotypes, *E. multilocularis* and other taeniids that occur in the same geographical area. Multiplex PCR in particular are a useful approach to multispecies detection. (Dinkel *et al.,* 2011; Trachsel *et al.,* 2007). Currently there are several published PCRs for the *E. granulosus* complex and *E. multilocularis* (Table 3) and their great value is an extremely high specificity to the extent that a result can be taken as an alternative to the finding of worms at necropsy or purgation. A practical and cost-effective way to undertake testing of dogs or foxes on a large-scale is to adopt a serial testing strategy based on primary screening of all samples using the coproELISA,

1 https://www.woah.org/en/what-we-offer/expertise-network/reference-laboratories/#ui-id-3

followed by testing of all positives using coproPCR ensuring that duplicate samples are taken from each animal and fixed appropriately for each technique.

Table 3. PCR primers used for coproDNA detection* (*modified from Craig* et al., *2015*). *Tissue indicates that the technique is also compatible with DNA extraction from metacestode tissues

LAMP: loop-mediated isothermal amplification

3. Serological tests

3.1. Intermediate hosts

Serological diagnosis of ovine echinococcosis has long been considered a potentially important tool for epidemiological studies in endemic areas, as well as for surveillance of control programmes. It has been known for many years that sheep infected experimentally with *E. granulosus* can mount detectable specific IgG responses within weeks. However, serum antibody levels varied greatly in natural infections resulting in reduced sensitivity and cross-reactions with *Taenia hydatigena* or *T. ovis* infected animals. At present this approach cannot replace necropsy (Craig *et al.,* 2015; McManus, 2014).

3.2. Definitive hosts

Serodiagnostic tests for canine echinococcosis were considered to have good potential for practical testing of dogs for *E. granulosus* infection and, initially, as a potential substitute for arecoline purgation. Diagnostic specificity was good (>90%) but sensitivity was generally poor (35–40%) with natural infections, and was much lower when compared directly with coproantigen detection (Jenkins *et al.,* 1990). Further research to assess existing or develop better recombinant antigens may improve the sensitivity of serological tests for canine echinococcosis.

There is mounting evidence of cases where dogs developed alveolar echinococcosis (AE) caused by the larval stage. AE in dogs is fast-developing and life-threatening. Frey *et al.* (2017) evaluated the diagnostic performance of several antigens for serological detection of AE in dogs. Excellent performance of ELISA with recombinant EM95 antigen in combination with Western blot was demonstrated. The test can potentially detect AE in the early stages of development. Since AE in dogs may be concomitant with the intestinal adult stage, it was suggested that dogs from endemic areas should be tested for *E. multilocularis* using available methods, including the EM95 ELISA, before relocation into non-endemic regions.

C. REQUIREMENTS FOR VACCINES

1. Background

1.1. Intermediate hosts

Application of an effective vaccine to reduce CE infection in livestock may have a substantial impact on the rate of transmission of the disease to humans (Lightowlers, 2006; Torgerson, 2003). A highly effective EG95 vaccine has been developed that can prevent infection with *E. granulosus s.s.* in the parasite's livestock intermediate hosts (Lightowlers *et al.,* 1996; Gauci *et al.,* 2011). Field trials of the vaccine have demonstrated that the vaccine reduces the level of cystic echinococcosis in sheep under natural conditions (Amarir *et al*., 2021; Larrieu *et al*., 2019). The ultimate aim of vaccination against *E. granulosus* is to reduce the parasite's transmission and reduce human exposure to cystic echinococcosis.

Two subcutaneous immunisations, approximately 1 month apart, induce protection against subsequent exposure to *E. granulosus* eggs. The vaccine is not believed to cure an infection existing prior to the animal being vaccinated. For that reason, young animals should receive their first vaccination around the time of weaning. The duration of immunity induced in young animals after a second vaccination is sufficient to protect them until 1 year of age, at which time a single booster vaccination elicits a strong protective response sufficient to induce long-lasting protection (Larrieu *et al*., 2019; Poggio *et al*., 2016). Hence, a vaccination programme involving two immunisations in recently weaned animals, followed by a single booster immunisation when animals are approximately 1 year of age, presents effective and practical programme.

The EG95 vaccine is manufactured in Argentina, China (People's Rep. of) and Morocco, and has gained regulatory approval in Morocco and a number of East and South Asian, and South American, countries.

1.2. Definitive hosts

Development of *E. granulosus* vaccines for dogs would ideally reduce worm fecundity and populations, and could be a valuable step towards the reduction (prevention) of the infection pressure on intermediate hosts, and thus reduce (prevent) infection in dogs. However, no clear evidence exists for immunologically-based protection against *Echinococcus* infection in definitive hosts. Attempts to actively immunise dogs against infection with *E. granulosus* have not produced consistent results.

2. Outline of production and minimum requirements for vaccines for intermediate hosts

The vaccine incorporates 50 µg of the EG95 antigen, expressed in *Escherichia coli*, together with adjuvant (Quil A or Montanide ISA 70 plus saponin) (Gauci *et al.,* 2011; Lightowlers *et al.,* 1996).

2.1. Characteristics of the seed

2.1.1. Quality criteria

Suitable *E. coli* strains (BB4 LE392.23 [F´ *lacI*^{q} ZΔM15 *proAB* Tn10 (Tet^{r})] or BL21 (DE3) F^{-}*omp*T *hsdS*$_{B}$ (r_{B}^{-}, m_{B}^{-}) *gal dcm* (DE3) for expression of recombinant vaccine antigen should be acquired from a source that has been established as sterile and pure (free of extraneous agents as described in Chapter 1.1.9 *Tests for sterility and freedom from contamination of biological materials intended for veterinary use* and those listed by the appropriate licensing authorities). The pGEX expression vector should be obtained from a source known to be free of extraneous agents. The EG95 DNA insert in the expression vector should be verified as having the sequence described (Gauci *et al.,* 2011; Lightowlers *et al.,* 1996).

2.2. Methods of manufacture

2.2.1. Procedure

Suitable *E. coli* strains are transformed with pGEX vector containing in-frame EG95 cDNA. Bacteria are cultured in a suitable medium such as Super Optimal Broth. Recombinant protein expression is induced by addition of isopropyl-ß-D-thiogalactosidase (IPTG) at a concentration of 0.2 mM with incubation for 3–5 hours, after which the culture supernatant is discarded and the bacterial pellets are resuspended in PBS, pH 7.4. After chilling on ice, *E. coli* are lysed by sonication, French Press or other suitable equipment. The extent of bacterial cell lysis is monitored by measuring an increase in the soluble proteins released from the ruptured cells by determination of protein concentration. Soluble and insoluble cellular proteins are separated by centrifugation. After a brief wash with PBS, insoluble proteins are solubilised in 8 M urea. Vaccine can be prepared from either the soluble fraction by glutathione agarose affinity purification as described by Lightowlers *et al.* (1996) or from the insoluble inclusion bodies as described by Gauci *et al.* (2011). Proteins are analysed by SDS-PAGE (sodium dodecyl sulphate polyacrylamide gel electrophoresis) and quantified by scanning densitometry and determining protein concentration according to Bradford (1976).

2.2.2. Requirements for ingredients

All ingredients used for vaccine production should comply with the requirements referred to in Chapter 1.1.8 *Principles of veterinary vaccine production*.

2.2.3. Final product batch tests

i) Sterility

Must comply with chapter 1.1.8.

ii) Safety

Batch safety testing is performed unless consistent safety of the product is demonstrated and approved in the regulatory approval dossier and the production process is approved for consistency with the standard requirements referred to in chapter 1.1.8.

This final product batch safety test is conducted to detect any abnormal local or systemic adverse reactions. Local and general reactions must be examined. The tests must be performed by administering the vaccine to the sheep in the recommended dose and recommended route of administration. Objective and quantifiable criteria to detect and measure adverse reactions should be used; these would include temperature changes of vaccinated and control groups.

iii) Batch potency

Sheep are immunised according to the recommended protocol (two subcutaneous injections, 3–4 weeks apart). IgG antibody responses to the EG95 antigen are determined 2 weeks after the second immunisation as described by Heath & Koolaard (2012).

CHAPTER 3.1.7

EPIZOOTIC HAEMORRHAGIC DISEASE (INFECTION WITH EPIZOOTIC HEMORRHAGIC DISEASE VIRUS)

SUMMARY

Epizootic haemorrhagic disease (EHD) is a vector-borne infectious noncontagious viral disease of domestic and wild ruminants, primarily white-tailed deer (Odocoileus virginianus) *and cattle. Sheep, goats and camelids might also be susceptible, but usually do not develop overt disease.*

EHD virus (EHDV) is transmitted between ruminant hosts by species of Culicoides *biting midges, thus EHD infections are strongly seasonal. White-tailed deer is the most severely affected species, with the peracute form having a high mortality rate. In cattle, clinical signs occur rarely but fever, anorexia, dysphagia, emaciation, ulcerative stomatitis, lameness, respiratory distress and erythema of the udder have been reported.*

Detection of the agent: *EHDV belongs to the family* Reoviridae*, genus* Orbivirus*, and shares many morphological and structural characteristics with the other members of the genus, in particular bluetongue virus (BTV).*

EHDV particles are non-enveloped but have a double capsid with an icosahedral symmetry. Within the virus core, 10 double-stranded RNA genomic segments code for seven structural proteins (VP) and at least four nonstructural proteins (NS). The protein VP2 of the outer core is the major determinant of serotype specificity, while the VP7 of the inner core possesses the serogroup-specific antigens. At least seven distinct serotypes have been identified and two new putative serotypes; there is however, some uncertainty regarding the exact number of serotypes and a panel of reference strains of EHDV is not yet officially recognised.

Assays for detection of EHDV in field samples include virus isolation in cell culture and EHD serogroup-specific reverse-transcription polymerase chain reaction (RT-PCR) tests. Suspected isolates can be identified by competitive (antigen-capture) and sandwich enzyme-linked immunosorbent assays (ELISAs). Serotype-specific RT-PCR assays have been developed for serotype identification of cell culture isolates. Isolates may also be identified by high throughput sequencing or virus neutralisation tests.

Serological tests: *Antibodies to EHDV may be first detectable from 8 days post-exposure. Neutralising antibodies and the virus can co-exist in the infected animal, likely because of the strong association between the EHDV and the red blood cells.*

For the detection of anti-EHDV antibodies in the sera of exposed animals, a specific monoclonal antibody-based competitive ELISA (C-ELISA) is recommended. The C-ELISA is a rapid test, detecting antibodies against the VP7 protein. Virus neutralisation (VN) tests may also be performed. VN testing is usually performed to identify exposure to specific EHDV serotypes. The VN test is more time-consuming (3–5 days) and labour intensive, and cross reactions among serotypes may preclude optimal results. Tests such as agar gel immunodiffusion and the indirect ELISA can be used, but have the major drawback of being unable to distinguish between antibodies to EHDV and BTV.

Requirements for vaccines: *In the USA, an autogenous vaccine that can be used only in captive wild deer has been administered. In Japan, a vaccine has been developed for use in cattle. Apart from these two limited settings, there has been little interest from laboratories and vaccine companies elsewhere in developing vaccines to control the disease or EHDV circulation.*

A. INTRODUCTION

Epizootic haemorrhagic disease (EHD) is an infectious noncontagious viral disease transmitted by insects of the genus *Culicoides*. Available data suggest that the species of *Culicoides* that transmit EHD virus (EHDV) are likely to be similar though not necessarily the same as those that transmit bluetongue virus (BTV) (Carpenter *et al.,* 2008).The disease affects both wild and domestic ruminants, particularly North American cervids, and, to a lesser degree, cattle (Bréard *et al.,* 2004), although many countries describe only asymptomatic infection (Gard & Melville, 1992; St George *et al.,* 1983). Sheep, goats and camelids may be susceptible to EHDV infection but their role as hosts is uncertain.

In susceptible species, EHDV may cause a disease with clinical manifestations similar to BTV infection. White-tailed deer (*Odocoileus virginianus*) are the species most severely affected with the peracute form characterised by fever, anorexia, respiratory distress, and severe oedema of the head and neck. Swelling of the tongue and conjunctivae can also be present. In the acute (or classical) form, these clinical signs may be accompanied by haemorrhages in many tissues including skin and heart, and animals may develop ulcers or erosions of the tongue, dental pad, palate, rumen and abomasum (Savini *et al.,* 2011).

Histopathological lesions include widespread vasculitis with thrombosis, endothelial swelling, haemorrhages and necrosis in many organs especially the tongue, salivary glands, fore-stomachs, aorta and papillary muscle of the left ventricle of the myocardium. Scattered grey plaques on the surface of the gall bladder mucosa were also described (Noon *et al.,* 2002).

While the majority of infections in cattle are subclinical, the serotypes 1, 2, 6 and 7 have been described as potentially pathogenic (Bréard *et al.,* 2004; Cêtre-Sossah *et al.,* 2014; Temizel *et al.,* 2009). The disease is characterised by fever, anorexia, ulcerative stomatitis, swelling of eyelids, respiratory distress, nasal and ocular discharge, redness and scaling of muzzle and lips, lameness, erythema of the udder and difficulty swallowing (Temizel *et al.,* 2009). Ibaraki disease in cattle is caused by a strain of EHDV-2 (Anthony *et al.,* 2009). Animals become dehydrated and emaciated, and in some cases death occurs due to aspiration pneumonia. The lesions are histologically characterised by hyaline degeneration, necrosis and mineralisation of striated muscle accompanied by an infiltration of neutrophils, lymphocytes and histiocytes (Ohashi *et al.,* 1999; Savini *et al.,* 2011).

Taxonomically, EHDV is classified in the *Orbivirus* genus of the family *Reoviridae* (Maclachlan & Osburn, 2004). It is a double-stranded RNA virus with a genome of 10 segments. At least some of the genome segments are able to undergo reassortment during mixed infections in the field (Allison *et al.,* 2010; Anbalagan *et al.,* 2014). Seven serotypes (and two new putative serotypes) are currently recognised, but there is not yet a widely accepted consensus on the exact number of serotypes (Anthony *et al.,* 2010; Maan *et al.,* 2017; Shirafuji *et al.,* 2017; Wright, 2013). The virus is stable at –70°C and in blood, tissue suspension or washed blood cells held at 4°C. EHDV on laboratory surfaces is susceptible to 95% ethanol and 0.5% sodium hypochlorite solution.

EHDV particles are composed of three protein layers. The outer capsid consists of two proteins, VP2 and VP5. Like BTV, VP2 is the primary determinant of serotype specificity. VP5, the other external protein, might also elicit neutralising antibodies (Savini *et al.*, 2011; Schwartz-Cornill *et al.*, 2008). This outer capsid is dissociated readily from the core particle, and leaves a bi-layered icosahedral core particle composed of two major proteins, VP7 and VP3, surrounding the transcriptase complex (VP1, VP4, and VP6) and the genomic RNA segments. VP7 is the serogroup-specific immuno-dominant protein and the protein used in serogroup specific enzyme-linked immunosorbent assays (ELISAs) (Saif, 2011). The viral RNA also encodes five nonstructural proteins (NS1 to NS5) (Belhouchet *et al.,* 2011).

As a vector-borne viral disease, the distribution of EHD is limited to the distribution of competent *Culicoides* vectors (Mellor *et al.,* 2008).The EHDV has been isolated from wild and domestic ruminants and arthropods in North America, Ecuador (Verdezoto *et al.,* 2018), the Caribbean region (Brown-Joseph *et al.,* 2019), French Guiana (Viarouge *et al.,* 2014), Asia, Africa and Australia, and more recently in countries surrounding the Mediterranean Basin including Algeria, Israel, Jordan, Morocco, Tunisia, and Turkey. No cases of EHDV infection have been reported in Europe. Outbreaks generally coincide with the peak of vector population abundance, so most cases of EHD occur in the late summer and autumn (Mellor *et al.,* 2008; Stallknecht & Howerth, 2004).

As EHDV is a vector-borne infection it may be difficult to control or eradicate once established. Unpredicted and uncontrollable variables such as climatic and geographical factors, as well as abundance of suitable EHDV insect vectors are all important for the outcome and persistence (or reappearance) of EHDV in an area. Furthermore, to date, there are no detailed studies on the effect of control measures applied in the countries where the disease has affected cattle. Sera prepared from viraemic animals may represent some risk if introduced parenterally into naive

animals. The most significant threat from EHDV occurs when virus is inoculated parenterally into susceptible animals. If appropriate *Culicoides* are present, virus can be transmitted to other hosts. Therefore, EHDV-infected animals must be controlled for the period of viraemia and protected against *Culicoides* by physical means.

There is no known risk of human infection with EHDV. Biocontainment measures should be determined by risk analysis as described in Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities.*

B. DIAGNOSTIC TECHNIQUES

Table 1. Test methods available for the diagnosis of EHD and their purpose

Method	Purpose					
	Population freedom from infection	Individual animal freedom from infection prior to movement	Contribute to eradication policies	Confirmation of clinical cases	Prevalence of infection – surveillance	Immune status in individual animals or populations post-vaccination
Detection of the agent[(a)]						
Real-time RT-PCR	–	+++	+	++	++	–
RT-PCR	–	++	+	++	++	–
Isolation in cell culture	–	++	–	++	–	–
Detection of immune response						
C-ELISA (serogroup specific)	+++	+++	+++	–	+++	++
VN (serotype specific)	++	++	++	–	++	+++
AGID	+	–	+	–	+	+
CFT	+	–	+	–	+	+

Key: +++ = recommended for this purpose; ++ recommended but has limitations;
+ = suitable in very limited circumstances; – = not appropriate for this purpose.
RT-PCR = reverse-transcription polymerase chain reaction; C-ELISA = competitive enzyme-linked immunosorbent assay;
VN = virus neutralisation; AGID = agar gel immunodiffusion test; CFT = complement fixation test.
[(a)]A combination of agent identification methods applied on the same clinical sample is recommended.

Clinical signs of EHD in wild ruminants and cattle are similar to those of BT in sheep and cattle, and they may be similar to signs found in other cattle diseases like bovine viral diarrhoea/mucosal disease, infectious bovine rhinotracheitis, vesicular stomatitis, malignant catarrhal fever and bovine ephemeral fever. Definitive diagnosis of EHDV infection therefore requires the use of specific laboratory tests.

1. Detection of the EHDV agent

1.1. *In-vitro* culture

1.1.1. Isolation in cell culture

The same diagnostic procedures are used for domestic and wild ruminants. Virus isolation can be attempted from the blood of viraemic animals, tissue samples including spleen, lung and lymph

nodes of infected carcasses, and from *Culicoides* spp. EHDV can be isolated by inoculation of cell cultures such as those of cattle pulmonary artery endothelial, baby hamster kidney (BHK-21), and African green monkey kidney (Vero) (Aradaib *et al.*, 1994), the latter two being the most commonly used for growing the virus. *Aedes albopictus* (e.g. C6/36) and *Culicoides variipennis* (Kc) cell lines may also be used for virus isolation (Batten *et al.,* 2011; Eschbaumer *et al.,* 2012; Gard *et al.*, 1989); as can embryonated chicken eggs, but with less sensitivity (Eschembauer *et al.,* 2012). Cytopathic effect (CPE), which occurs only in mammalian cell lines, usually appears between 2 and 7 days post-inoculation, however a blind passage may be required.

Below is a general virus isolation procedure in cell culture that can be modified according to individual laboratory needs. Incubation of cell cultures for EHDV isolation is usually performed in a humid 5% CO_2 atmosphere.

i) For tissues from clinical cases, prepare a 10–30% tissue suspension in cell culture or other appropriate medium containing antibiotics. Centrifuge and save the supernatant for virus isolation.

ii) For uncoagulated whole blood, centrifuge the blood (0.2 ml) to separate the red blood cells (RBC) and plasma. Discard the plasma and replace with phosphate-buffered saline (PBS, pH 7.4). Centrifuge the blood again to separate the RBC. Perform three total washes with PBS. Add 0.4 ml of sterile distilled water to lyse the RBC. Cells may alternatively be lysed by sonication. Add 1.6 ml of PBS to the lysed RBC and save for virus isolation.

iii) Discard medium from the vessel containing fresh monolayer cells (1–3 days old).

iv) Inoculate the cells with a fraction of the clarified tissue or lysed RBC suspension, or previous passage cell culture.

v) Incubate at 34–37°C for 1 hour. Cell culture flask caps should be loosened or vented caps should be used to allow for gas transfer.

vi) Discard the inoculum and wash the monolayer with medium containing antibiotics once or twice. Add maintenance medium and return to the incubator.

vii) Observe the cells for CPE regularly. CPE is only observed in mammalian cell lines and usually appears between 2 and 7 days post-inoculation.

viii) If no CPE appears, a second and third passage should be attempted. Scrape the cells by using a scraper or freeze–thaw the cells once and inoculate fresh cultures.

ix) If CPE is present suggesting the presence of virus, the identity of the isolate may be confirmed by reverse-transcription polymerase chain reaction (RT-PCR), antigen capture ELISA, immunofluorescence, or virus neutralisation.

1.1.2. Serogroup identification of isolates

i) *Molecular methods*

See Section 1.2.1 for PCR methods.

ii) *Immunological methods*

Orbivirus isolates are typically serogrouped on the basis of their reactivity with specific standard antisera that detect proteins, such as VP7, that are conserved within each serogroup. The cross-reactivity between members of the EHD and BT serogroups raises the possibility that an isolate of BTV could be mistaken for EHDV on the basis of a weak immunofluorescence reaction with a polyclonal anti-EHDV antiserum. For this reason, an EHDV serogroup-specific monoclonal antibody (MAb) can be used. A number of laboratories have generated such serogroup-specific reagents (Luo & Sabara, 2005; Mecham & Jochim, 2000; Mecham & Wilson, 2004; White *et al.,* 1991). Commonly used methods for the identification of viruses to serogroup level are as follows.

a) Immunofluorescence

Monolayers of BHK-21 or Vero cells on chamber slides (glass cover-slips) are infected with either tissue culture-adapted virus or virus in insect cell lysates. After 24–48 hours at 37°C,

or after the appearance of a mild CPE, infected cells are fixed with agents such as paraformaldehyde, acetone or methanol, dried and viral antigen detected using anti-EHDV antiserum or EHDV-specific MAbs and standard immunofluorescent procedures.

b) Serogroup-specific sandwich ELISA

The serogroup-specific sandwich ELISA is able to detect EHDV in infected insects and tissue culture preparations (Thevasagayam *et al*., 1996). The assay is EHDV specific, with no cross-reactions with other orbiviruses such as BTV and African horse sickness virus (AHSV).

1.1.3. Serotype identification of EHDV isolates

i) *Molecular methods*

a) Polymerase chain reaction

Recent genome identification of EHDV isolates has enabled molecular identification of serotype and/or topotype by RT-PCR using serotype-specific primers followed by sequencing (Maan *et al.*, 2010; Sailleau *et al.,* 2012).

b) High throughput sequencing

High throughput sequencing may be performed on isolates with or without serotype-specific primers. Sequences may be compared with the GenBank library for serotype identity.

ii) *Immunological techniques*

a) Serotyping by virus neutralisation

There is a variety of tissue culture-based methods available to detect the presence of neutralising anti-EHDV antibodies. Cell lines commonly used are BHK-21 and Vero. Two methods to serotype EHDV are outlined briefly below. EHDV serotype-specific antisera generated in guinea-pigs or rabbits have been reported to have less serotype cross-reactivity than those made in cattle or sheep. It is important that antiserum controls be included. The WOAH Reference Laboratory can supply control positive sera.

- Plaque reduction

  The virus to be serotyped is serially diluted and incubated with either no antiserum or with a constant dilution of individual standard antisera to a panel of EHDV serotypes. Virus/antiserum mixtures are added to monolayers of cells. After 1 hour adsorption at 37°C and 5% CO_2, and removal of inoculum, monolayers are overlaid with cell culture medium containing 0.8–0.9% agarose. Plates/flasks are incubated at 37°C and 5% CO_2. After 4 days' incubation, a second overlay containing 0.01% (1 part per 10,000) neutral red and 0.8–0.9% agarose in cell culture medium is applied and the plates/flasks are incubated at 37°C and 5% CO_2. Flasks are examined daily for visible plaques for up to 3 more days. The neutralising antibody titres are determined as the reciprocal of the serum dilution that causes a fixed reduction (e.g. 90%) in the number of plaque-forming units. The unidentified virus is considered serologically identical to a standard serotype if the latter is run in parallel with the untyped virus in the test, and is similarly neutralised.

- Microtitre neutralisation

  Approximately 100 $TCID_{50}$ (50% cell culture infective dose) of the standard or serial dilution of the untyped virus is added in 50 µl volumes to test wells of a flat-bottomed microtitre plate and mixed with an equal volume of a constant dilution of standard antiserum in tissue culture medium. After 1 hour incubation at 37°C and 5% CO_2 approximately 10^4 cells are added per well in a volume of 100 µl, and the plates incubated for 3–5 days at 37°C and 5% CO_2. The test is read using an inverted microscope. Wells are scored for the degree of CPE observed. Those wells that contain cells only or cells and antiserum, should show no CPE. In contrast, wells containing cells and virus should show 75–100% CPE. The unidentified virus is considered to be serologically identical to a standard EHDV serotype if both are

neutralised in the test to a similar extent, i.e. 75% and preferably 100% protection of the monolayer is observed.

1.2. Molecular methods – detection of nucleic acid

1.2.1. Conventional reverse-transcription polymerase chain reaction

In recent years, several efforts were directed towards the development of innovative molecular techniques such as the RT-PCR for the rapid detection of EHDV nucleic acid (Aradaib *et al.* 2003; Clavijo *et al.*, 2010; Wilson *et al.*, 2009; Viarouge *et al.,* 2014). RT-PCR allows the detection of EHDV RNA in blood samples and other tissues. Moreover, serotype-specific RT-PCRs targeting segment 2 of the viral RNA have been developed (Brodie *et al.*, 1998; Maan *et al.*, 2010; Sailleau *et al.,* 2012), as well as multiplex real-time RT-PCRs for the discrimination between EHDV and BTV (Wilson *et al.*, 2009; Yin *et al.*, 2010). Although RT-PCR has high sensitivity and specificity, RT-PCR-based diagnosis should be interpreted with caution: the RT-PCR technique detects viral RNA with a very high level of sensitivity, but this does not necessarily indicate the presence of infectious virus. The duration of EHDV positivity by RT-PCR in blood is not known, but there is evidence that it lasts longer than the period over which infectious virus can be isolated, as demonstrated for BTV.

The capacity of RT-PCR assays to detect very small numbers of nucleic acid molecules means that such tests are exquisitely sensitive to contamination by extraneous nucleic acids. The latter may include any primers in use in the laboratory or previously amplified polynucleotides. It is critical therefore to have a 'clean' area containing all equipment necessary for reagent and test preparation and a separate area with its own equipment for amplification. Impervious gloves should be worn and changed frequently at all stages of the procedure, particularly after working with sample RNA or amplified DNA. This will help protect reagents and samples from contamination by ubiquitous RNAses and other agents and from cross-contamination by DNA.

i) *RNA extraction from blood, insects and tissue samples*

A large variety of commercial kits are available; the RNA extraction step should be appropriate to the sample to be tested (e.g. blood vs tissue) and can be performed following directions suggested by the manufacturers.

ii) *Reverse-transcription polymerase chain reaction*

Several kits for one-step RT-PCR are currently available on the market. Alternatively, a double step procedure consisting of an initial RT step followed by cDNA amplification could be performed. Most of these methods still require a proper validation protocol. General recommendations that might be modified depending upon local/case-specific needs are indicated below. The method described by Aradaib *et al.* (2003) directed to S5 of EHDV has been taken as an example of conventional RT-PCR.

Primer sequences
For: 5'-TCG-AAG-AGG-TGA-TGA-ATC-GC-3';
Rev: 5'-TCA-TCT-ACT-GCA-TCT-GGC-TG-3'

a) Primer stock solutions are diluted to a final concentration of 10 pmol/µl.

b) One-step RT-PCR reaction tubes are labelled and 4.0 µl of primer mix is added to each tube. The tubes are held on ice.

c) Next, 4 µl of test, positive and negative control RNA samples are added to 4 µl of the primer mix in RT-PCR tubes.

d) Heat denaturation: 95°C for 5 minutes, then ice for further 3 minutes.

e) One-step RT-PCR mix is prepared, based on direction of the manufacturer, containing reagents in sufficient volume for the number of samples being tested.

f) One-step mix is added to the denatured mix to a final volume of 50 µl.

g) The tubes are placed in a thermal cycler programmed for reverse transcription and cDNA amplification as suggested by the manufacturer.

iii) *Electrophoretic analysis of RT-PCR product*

The presence of EHDV in the RT-PCR products could then be visualised by using standard electrophoretic analysis procedures.

1.2.2. Real-time reverse-transcription polymerase chain reaction

Assays based on RT-PCR have been used to detect EHDV RNA in clinical specimens. Serogroup-specific RT-PCRs are directed toward the highly conserved genes of EHDV such as S9 or S10 or less highly conserved genes including S3. However, none of these assays is able to discriminate simultaneously all EHDV serotypes. There is limited (or no) information regarding the detectability of published assays for all serotypes, a real-time RT-PCR (Clavijo *et al.*, 2010) is reported to recognise and quantify all EHDV serotypes. The targeted gene of this method is represented by the NS1 gene. More recently, new real-time RT-PCRs have been described for the detection and typing of seven serotypes of EHDV (Maan *et al.,* 2017; Viarouge *et al.,* 2015).

The real-time RT-PCR described below (Viarouge *et al.,* 2015) is a duplex pan-EHDV real-time RT-PCR assay that amplifies a portion of segment 9 of all EHDV strains coupled with a real-time RT-PCR that amplifies the beta-actin RNA of ruminant cells (housekeeping gene). Moreover, a set of seven duplex serotyping real-time RT-PCR assays that specifically amplify both the EHD segment 2 portion of each serotype and the beta-actin gene is described. The Ct (cycle threshold) value obtained with the real-time RT-PCR that amplifies the housekeeping gene is used to verify the integrity of the total RNA extracted and the absence of inhibitors that can interact during the RT-PCR steps for each biological sample tested. These assays were developed and validated to detect and serotype EHDV for application to biological samples from the field.

Assay type	Primers/Probe Name	Sequence (5'–3')
Pan EHDV	EHDV_Seg9_F_7-25	AAT-TGC-GCA-TGT-CAG-CTG-C
	EHDV_Seg9_R_76-55	TTT-AAT-TCC-TCG-GTC-GAA-CGT-T
	EHDV_Seg9_P_29-44	FAM-TTT-GCT-CGC-ACC-CGG-T-MGB
Type EHDV1	EHDV1_Seg 2_F_8-31	TGT-GTC-AGG-ATG-GAG-GAC-ATT-AAC
	EHDV1_Seg 2_R_ 231-255	CGA-ATT-ATT-CCR-GTR-CTT-AAC-GCT-T
	EHDV1_Seg2_P_ 128-143	FAM-CCG-CAT-CAA-ATG-TAT-G-MGB
	EHDV1_Seg2_P'_128-141	FAM-CCG-CAC-CAG-ATG-TAT-MGB
Type EHDV2	EHDV2_Seg2_F_1642-1665 (W)	CCT-TTA-AGA-TAA-GAC-GGG-TCG-AGA
	EHDV2_Seg2_F'_1640-1666 (E)	GTC-CTT-TAA-GGT-AAG-ACG-GGT-AGA-GAT
	EHDV2_Seg2_R_1798-1770	CTC-AAG-ATA-TTA-CCG-GTT-AAG-CAT-AGA-GT
	EHDV2_Seg2_R'_1788-1170	TGC-CGG-TCA-TAC-AGA-ACG-C
	EHDV2_Seg2_P_1728-1743	FAM-AAC-GAG-ATG-TGG-CTT-C-MGB
Type EHDV4	EHDV4_Seg2_F_2573-2591	TAT-CAA-GCG-ACC-CAG-TCG-C
	EHDV4_Seg2_R_2771-2743	CGT-ATG-ACA-TTC-TGC-AAG-TCA-GC
	EHDV4_Seg2_P_2635-2653	FAM-CAC-ATC-TAC-GGA-TAC-TGT-G-MGB
Type EHDV5	EHDV5_Seg2_F_403-424	ACG-AAT-CGG-AGG-ATA-CGG-ATC
	EHDV5_Seg2_R_522-501	TCG-CGT-ATG-ATC-ACA-CTG-GTC-T
	EHDV5_Seg2_P_471-489	FAM-ACT-ATC-GGT-AGT-GGT-GTT-C-MGB
Type EHDV6	EHDV6_Seg2_F_560-582	GGA-TCT-GGA-ACG-TGC-TAT-GAT-CT
	EHDV6_Seg2_F'_561-582	GTT-CCG-GGA-CAT-GCT-ATG-ATC-T
	EHDV6_Seg2_R_734-714	CAG-CCT-GAA-TCT-TCG-TTT-GCT
	EHDV6_Seg2_R'_734-715	CCG-CCT-GAA-TTT-TTG-TTT-GC
	EHDV6_Seg2_P_686-702	FAM-ATA-ACG-AAC-AGG-GAG-CC-MGB

Assay type	Primers/Probe Name	Sequence (5'–3')
Type EHDV7	EHDV7_Seg2_F_2490-2508	CGA-GAG-GAA-CCG-ACC-GAA-G
	EHDV7_Seg2_F'_2490-2512	CGA-GAA-GAG-CCG-ATT-GAA-GAA-G
	EHDV7_Seg2_R_2627-2605	GCT-TAA-ATG-CGT-ATT-CAT-GGG-AT
	EHDV7_Seg2_R'_2629-2605	GTG-CTT-AAA-TGC-GTA-TTC-ATA-GGG-T
	EHDV7_Seg2_P_2520-2537	FAM-ACT-GTA-TGG-CCG-TAT-CTA-MGB
Type EHDV8	EHDV8_Seg2_F_822-846	ACG-ATC-CTA-TAA-TAT-CAC-GCT-TGG-A
	EHDV8_Seg2_R_897-878	TCT-TCG-ATC-CGC-TCA-CTG-C
	EHDV8_Seg2_P_853-869	FAM-AGC-TGA-TGA-ATG-GAT-GC-MGB

Primer and probe sequences for endogenous gene (Toussaint *et al.,* 2007)

Primers:
ACT_F_1005–1029 (5'-CAG-CAC-AAT-GAA-GAT-CAA-GAT-CAT-C-3'), ACT_R_1135–1114 (5'-CGG-ACT-CAT-CGT-ACT-CCT-GCT-T-3').

Probe sequences
Probe: ACT_P_1081–1105 (VIC-TCG-CTG-TCC-ACC-TTC-CAG-CAG-ATG-T-TAMRA).

The PCR amplification is performed using a real-time one-step RT-PCR kit. The mixtures contain 1× buffer, 0.5 µM of each EHDV-primer, 0.25 µM EHDV-probe, 0.375 µM of each beta-actin-primers, 0.25µM beta-actin-probe, 1 µl of enzyme mix, and 5 µl of denaturated template in a total of 20 µl of reaction volume. After RNA denaturation by heating at 95°C for 3 minutes, 5 µl of denaturated RNA was added to the mix and the amplifications were carried out using the same cycling parameters for all of the assays: 45°C for 10 minutes, 95°C for 10 minutes followed by 40 cycles of 95°C for 15 seconds and 60°C for 1 minute. Fluorescence was measured during the 60°C annealing/extension step. Ct values were measured at the point at which the sample fluorescence signal crossed a threshold value (the background level). Negative results (for assays that did not exceed this signal level) are reported as 'No Ct'.

The Viarouge *et al.* (2015) method was validated according to the WOAH Validation Standard (except for the proficiency test, which was not undertaken). The real-time RT-PCR does not detect any of the 27 serotypes of BTV.

2. Serological methods

Following infection with EHDV, antibodies may be detectable from 8 days post-infection (Breard *et al.,* 2013; Eschbaumer *et al.,* 2012; Quist *et al.*, 1997). Like BTV, EHDV-infected animals may have neutralising antibodies and EHD viraemia at the same time; this is likely to be because of the strong association between the viruses and the RBCs. Duration of acquired immunity is still unknown but evidence from natural infections suggests it may last for life. A variety of serological methods, varying in sensitivity and specificity, are available to detect EHDV serogroup- and serotype-specific antibodies.

2.1. Competitive enzyme-linked immunosorbent assay (C-ELISA)

The EHD competitive ELISA (C-ELISA) was developed to measure EHDV-specific antibody without detecting cross-reacting antibody to other orbiviruses. These techniques making use of MAbs against EHDV VP7 are able to detect EHDV serogroup-specific antibodies (Luo & Sabara, 2005; Mecham & Jochim, 2000; Mecham & Wilson, 2004; White *et al.,* 1991), and currently are the preferred technique.

2.1.1. Test procedure

There are several test procedures described, and commercial kits are available. The following procedure gives one example of an EHD C-ELISA. The technique is similar to others except that in this technique the recombinant *Baculovirus*-expressed VP7 is captured by rabbit polyclonal anti-VP7-antibodies previously adsorbed to the wells (Mecham & Wilson, 2004).

i) 96-well microtitre plates are coated with 100 µl of the recombinant VP7 expressed in *Baculovirus* overnight at 4°C (Luo & Sabara, 2005), and diluted in 0.05 M carbonate buffer, pH 9.6.

ii) The plates are washed three times with PBST (0.01 M PBS containing 0.05% or 0.1% Tween 20, pH 7.4) and then blocked for 1 hour with 5% dry milk at room temperature.

iii) After being washed with PBST, 100 µl of test sera is added in duplicate at a single dilution, either 1/5, 1/10 or 1/20 in PBST containing 2.5% dry milk.

iv) Immediately, 100 µl of a predetermined dilution of MAb diluted in PBST is added to each well. MAb control wells contain diluent buffer in place of test serum.

v) Plates are incubated for 1 hour at 37°C and then further washed with PBST as described above

vi) After washing, wells are filled with 100 µl of an appropriate dilution of horseradish peroxidase-secondary antibody in PBST.

vii) Following incubation for 1 hour at 37°C, the conjugate solution is discarded and plates are washed three times using PBST. Wells are filled with 100 µl substrate solution and the plates are shaken at room temperature for 30 minutes.

viii) The reaction is stopped by addition of appropriate stopping reagent, and after blanking the ELISA reader on wells containing substrate and stopping reagent, the absorbance values are measured by using appropriate filters.

ix) Results are expressed as per cent inhibition and are derived from the mean absorbance values for each sample by the following formula:

% inhibition = 100 – [(mean absorbance test sample)/(mean absorbance MAb control) × 100].

NB: Some laboratories prefer to use a negative control serum that has previously been shown to have a percentage inhibition of zero as an alternative to the MAb control.

x) Percentage inhibition values >50% are considered to be positive. Inhibition between 40% and 50% is considered to be suspicious. The results of the test sera duplicates can vary as long as the results do not lie either side of the positive cut-off.

xi) Strong and weak positive sera and a negative serum should be included on each plate. The weak positive should give 60–80% inhibition and the negative should give less than 40% inhibition.

Commercially produced C-ELISAs based on recombinant VP7 and anti-VP7 MAb are now available. These commercial assays are routinely used in many laboratories across the world.

2.2. Virus neutralisation

The reference method for the identification and quantification of antibodies against EHDV serotypes present in test samples is the VN test. This technique detects and quantifies serotype-specific antibodies. The main disadvantage of the technique is that all suspected virus serotypes must be included in the assay, consequently, it can be a very time consuming and labour intensive test to perform. The VN test requires 3–5 days to be completed (Pearson *et al.,* 1992).

2.2.1. Test procedure

Cell lines commonly used are BHK-21 and Vero cells. A titre greater than or equal to 1/10 is usually considered specific for EHDV.

EHDV serotype-specific antisera generated in guinea-pigs or rabbits have been reported to have less serotype cross-reactivity than those made in cattle or sheep. It is important that antiserum controls be included.

i) 50µl of serial sera dilutions, from 1/10 to 1/1280, are added to each test well of flat-bottomed microtitre plates and each mixed with an equal volume of known EHDV serotypes (100 CID_{50}). The plates are incubated at 37°C in 5% CO_2.

ii) After 1 hour of incubation, approximately 10^4 Vero cells are added per well in a volume of 100 µl, of minimal essential medium (MEM) containing antibiotics and, after incubation for 4–6 days, the test is read using an inverted microscope.

iii) Wells are scored for the degree of CPE observed. A sample is considered positive when it shows 75% to preferably 100% CPE inhibition at the lowest dilution (1/10). The serum titre represents the highest serum dilution capable of reducing more than 75% CPE in cell culture.

2.3. Complement fixation

The complement fixation test (CFT) is sensitive and specific for EHDV diagnosis and was used until 1980 for diagnosis and certification of animals for export. The test is serogroup-specific and inexpensive with a sensitivity similar to the virus neutralisation (VN) and agar gel immunodiffusion (AGID) tests. CFT allows detection and quantification of antibodies for 4–12 months after infection but is less reliable after this period (Pearson *et al.*, 1992). CFT is particularly useful for detecting recent EHDV infections but not for detecting older infections.

2.4. Agar gel immunodiffusion

The AGID was widely used to detect EHDV antibodies from sera of infected animals (Dubay *et al.*, 2004). In the past this test was used for animal trade. It is simple, economical and the antigen used in the assay is relatively easy to generate. However, the disadvantage of the AGID is its lack of specificity in that it cannot discriminate between BTV and EHDV. Thus AGID positive sera should be retested using a serogroup-specific test, at least in those areas where BTV and EHDV may be co-circulating. Furthermore, although semi-quantitative the result of AGID is generally reported out as positive or negative. The AGID can detect antibodies from 5–15 days after infection to 2 years or more (Pearson *et al.*, 1992).

C. REQUIREMENTS FOR VACCINES

As an effort to control the disease, vaccines were developed in USA for captive wildlife deer farmers and in Japan to be used in cattle. Apart from these two limited settings, there has only been minor interest from laboratories and biologicals companies elsewhere to develop vaccines to control the disease or the virus circulation. Autogenous inactivated vaccines have been prepared in North America from EHDV isolates originating from ill or dead animals in affected premises. Their use must be approved by government authorities. Prior to release, these vaccines are tested for purity and safety. To make the products available expediently, autogenous vaccines are not tested for efficacy. Most of the applications are by deer farmers. As the vaccines use inactivated virus, two doses given 2–4 weeks apart are generally necessary to initially immunise the animals and a yearly booster is recommended.

In Japan, both live modified and inactivated vaccines have been developed to control Ibaraki disease. The live attenuated vaccine derived from the Ibaraki-2 strain was used following the outbreaks in 1980s and has been demonstrated to be safe and effective. The vaccine has to be administered once subcutaneously during the low vector season. The inactivated vaccine includes bovine ephemeral fever and Ibaraki viruses grown in cell cultures and inactivated by formalin, as an aluminium-gel adjuvanted vaccine. In Japan both vaccines are used on a voluntary basis according to the epidemiological situation.

CHAPTER 3.1.8.

FOOT AND MOUTH DISEASE (INFECTION WITH FOOT AND MOUTH DISEASE VIRUS)

SUMMARY

Foot and mouth disease (*FMD*) *is a highly contagious viral disease of mammals and has a great potential for causing severe economic loss in susceptible cloven-hoofed animals. There are seven serotypes of FMD virus* (*FMDV*), *namely, O, A, C, SAT 1, SAT 2, SAT 3 and Asia 1. Infection with one serotype does not confer immunity against another. FMD cannot be differentiated clinically from other vesicular diseases, such as swine vesicular disease, vesicular stomatitis, vesicular exanthema and Seneca Valley virus infection. Laboratory diagnosis of any suspected FMD case is therefore a matter of urgency.*

Typical cases of FMD are characterised by a vesicular condition of the feet, buccal mucosa and, in females, the mammary glands. Clinical signs can vary from mild to severe, and fatalities may occur, especially in young animals. In some species the infection may be subclinical, e.g. African buffalo (Syncerus caffer). *The preferred tissue for diagnosis is epithelium from unruptured or freshly ruptured vesicles or vesicular fluid. Where collecting this is not possible, blood and/or oesophageal–pharyngeal fluid samples taken by probang cup in ruminants or throat swabs from pigs provide an alternative source of virus. Myocardial tissue or blood can be submitted from fatal cases, but vesicles are again preferable if present.*

It is vital that samples from suspected cases be transported under secure conditions and according to international regulations. They should only be dispatched to authorised laboratories.

Laboratory diagnosis of FMD is by virus isolation or by the demonstration of FMD viral antigen or nucleic acid in samples of tissue or fluid. Detection of virus-specific antibody can also be used for diagnosis, and antibodies to viral nonstructural proteins (*NSPs*) *can be used as indicators of infection, irrespective of vaccination status. Confirmation of a case of FMD should take account of all relevant clinical, epidemiological and laboratory findings.*

Detection and identification of the agent: *The presence of FMD virus is confirmed by demonstration of specific antigen or nucleic acid, with or without prior amplification of the virus in cell culture* (*virus isolation*). *Due to the highly contagious nature and economic importance of FMD, the laboratory diagnosis and serotype identification of the virus should be done in a laboratory with an appropriate level of bio-containment, determined by risk analysis in accordance with Chapter 1.1.4* Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*.*

Enzyme-linked immunosorbent assays (*ELISA*) *can be used to detect FMD viral antigens and for serotyping. Lateral flow devices* (*LFD*) *are also becoming more readily available and can also be used to detect FMD viral antigens. The ELISA has replaced complement fixation* (*CF*) *in most laboratories as it is more specific and sensitive and it is not affected by pro- or anti-complement factors. If the sample is inadequate or the diagnosis remains uncertain, sample materials can be tested by reverse transcription polymerase chain reaction* (*RT-PCR*) *or virus isolation using susceptible cell to amplify any nucleic acid or live virus that may be present. The cultures should preferably be of primary bovine* (*calf*) *thyroid, but pig, lamb or calf kidney cells, or cell lines of comparable sensitivity may be used. Once a cytopathic effect* (*CPE*) *is complete in the cultures, harvested fluids can be tested for FMDV using ELISA, CF or RT-PCR.*

Serological tests: *The demonstration of specific antibodies to structural proteins in nonvaccinated animals is indicative of prior infection with FMDV. This is particularly useful in mild cases or where epithelial tissue cannot be collected. Tests for antibodies to some NSPs of FMDV are useful in*

providing evidence of previous or current viral replication in the host, irrespective of vaccination status. NSPs, unlike structural proteins, are highly conserved and therefore are not serotype specific and as a consequence, the detection of these antibodies is not serotype restricted.

Virus neutralisation tests (VNTs) and ELISAs for antibodies to structural proteins are used as serotype-specific serological tests. VNTs depend on tissue cultures and are therefore more prone to variability than ELISAs; they are also slower and subject to contamination. ELISAs for detection of antibodies have the advantage of being faster, and are not dependent on cell cultures. The ELISA can be performed with inactivated or recombinant antigens, thus requiring less restrictive biocontainment facilities.

Requirements for vaccines: *Inactivated virus vaccines of varying composition are available commercially. Typically, virus is used to infect a suspension or monolayer cell culture and the resulting preparation is clarified, inactivated with ethyleneimine and concentrated. The antigen is usually blended with oil or aqueous adjuvant for vaccine formulation. Many FMD vaccines are multivalent to provide protection against the different serotypes, or to accommodate antigenic diversity likely to be encountered in a given field situation.*

The finished vaccine must be shown to be free from residual live virus. This is most effectively done using in-vitro *tests on concentrated inactivated virus preparations prior to formulation of the vaccine and freedom from live virus is subsequently confirmed during* in-vivo *and/or* in-vitro *tests on the finished product. Challenge tests are also conducted in vaccinated cattle to establish a* PD_{50} *(50% protective dose) value or protection against generalised foot infection (PGP), although a serological test is considered to be satisfactory where a valid correlation between protection, and specific antibody response has been established.*

FMD vaccine production facilities should also have an appropriate level of bio-containment, determined by risk analysis in accordance with Chapter 1.1.4.

Diagnostic and reference reagents are available from the WOAH Reference Laboratories for FMD or the FAO (Food and Agriculture Organization of the United Nations) World Reference Laboratory for FMD (The Pirbright Institute, UK).

A. INTRODUCTION

Foot and mouth disease (FMD) is caused by a virus of the genus *Aphthovirus*, family *Picornaviridae*. There are seven serotypes of FMD virus (FMDV), namely O, A, C, SAT 1, SAT 2, SAT 3, and Asia 1, that infect cloven-hoofed animals. Infection with any one serotype does not confer immunity against another. Within serotypes, many strains can be identified by biochemical and immunological tests.

Of the domesticated species, cattle, pigs, sheep, goats and water buffalo (*Bubalus bubalis*) are susceptible to FMD (Food and Agricultural Organization of the United Nations [FAO]; 1984). Many species of cloven-hoofed wildlife may become infected, and the virus has occasionally been recovered from other species as well. Amongst the camelidae, Bactrian camels and new world camelids have been shown to be susceptible (Larska *et al*., 2009). In Africa, SAT serotypes of FMD viruses are often maintained by African buffalo (*Syncerus caffer*). There is periodic spillover of infection into livestock or sympatric cloven-hoofed wildlife. Elsewhere in the world, cattle are usually the main reservoir for FMD viruses, although in some instances the viruses involved appear to be specifically adapted to pigs (such as the pig-adapted Cathay strain of type O FMDV) and that requires cells of porcine origin for primary isolation. Small ruminants can play an important role in the spread of FMDV, but it is not clear whether the virus can be maintained in these species for long periods in the absence of infection of cattle. Strains of FMDV that infect cattle have been isolated from wild pigs, antelope and deer. The evidence indicates that, in the past, infection of deer was derived from contact, direct or indirect, with infected domestic animals, and that apart from African buffalo, wildlife has not, so far, been shown to be able to maintain FMD viruses independently for more than a few months.

Infection of susceptible animals with FMDV can lead to the appearance of vesicles on the feet, in and around the oral cavity, and on the mammary glands of females. The vesicles rupture and then heal whilst coronary band lesions may give rise to growth arrest lines that grow down the side of the hoof. The age of lesions can be estimated from these changes as they provide an indicator of the time since infection occurred (UK Ministry of Agriculture, Fisheries and Food; 1986). Mastitis is a common sequel of FMD in dairy cattle. Vesicles can also occur at other sites, such as

inside the nostrils and at pressure points on the limbs – especially in pigs. The severity of clinical signs varies with the strain of virus, the exposure dose, the age and breed of animal, the host species and the immunity of the animal. The signs can range from a mild or inapparent infection to one that is severe. Death may result in some cases. Mortality from a multifocal myocarditis is most commonly seen in young animals: myositis may also occur in other sites.

On premises with a history of sudden death in young cloven-hoofed livestock, close examination of adult animals may often reveal the presence of vesicular lesions if FMD is involved. The presence of vesicles in fatal cases is variable.

In animals with a history of vesicular disease, the detection of FMDV in samples of vesicular fluid, epithelial tissue, oesophageal–pharyngeal (OP) sample, milk, or blood is sufficient to establish a diagnosis. Diagnosis may also be established by the detection of FMDV in the blood, heart or other organs of fatal cases. A myocarditis may be seen macroscopically (the so-called "tiger heart") in a proportion of fatal cases.

FMD viruses may occur in all the secretions and excretions of acutely infected animals, including expired air. Transmission is generally effected by direct contact between infected and susceptible animals or, more rarely, indirect exposure of susceptible animals to the excretions and secretions of acutely infected animals or uncooked meat products. Following recovery from the acute stage of infection, infectious virus disappears with the exception of low levels that may persist in the oropharynx of some ruminants. Live virus or viral RNA may continue to be recovered from oropharyngeal fluids and cells collected with a probang cup. FMD virus has also been shown to persist in a nonreplicative form in lymph nodes (Juleff *et al*., 2008). Animals in which the virus persists in the oropharynx for more than 28 days after infection are referred to as carriers. Pigs do not become carriers. Circumstantial evidence indicates, particularly in the African buffalo, that carriers are able, on rare occasions, to transmit the infection to susceptible domestic animals with which they come in close contact: the mechanism involved is unknown. The carrier state in cattle usually does not persist for more than 6 months, although in a small proportion, it may last up to 3 years. In African buffalo, individual animals have been shown to harbour the virus for at least 5 years, but it is probably not a lifelong phenomenon. Within a herd of buffalo, the virus may be maintained for 24 years or longer. Sheep and goats do not usually carry FMD viruses for more than a few months, whilst there is little information on the duration of the carrier state in Asian buffalo species and subspecies.

FMD is considered a negligible zoonotic risk. However, because of its highly contagious nature for animals and the economic importance of FMD, all laboratory manipulations with live viral cultures or potentially infected/contaminated material such as tissue and blood samples must be performed at an appropriate containment level determined by biorisk analysis (see Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities*. Countries lacking access to appropriate containment facilities should send specimens to a WOAH FMD Reference Laboratory. Vaccine production facilities should also meet these containment requirements.

Diagnostic and standard reagents are available in kit form or as individual items from WOAH Reference Laboratories for FMD. The use of inactivated antigens in the enzyme-linked immunosorbent assay (ELISA), as controls in the antigen-detection test or to react with test sera in the liquid-phase blocking or solid-phase competitive ELISA, reduces the disease security risk involved compared with the use of live virus. Reagents are supplied freeze-dried or in glycerol or nonglycerinated but frozen and can remain stable at temperatures between +1°C and +8°C, –30°C and –5°C and –90°C and –50°C, respectively, for many years. There are a number of commercially available diagnostic test kits, for the detection of virus antigens or antibodies.

B. DIAGNOSTIC TECHNIQUES

Table 1. Test methods available for the diagnosis of FMD and their purpose

Method	Purpose					
	Population freedom from infection	Individual animal freedom from infection prior to movement	Contribute to eradication policies	Confirmation of clinical cases	Prevalence of infection – surveillance	Immune status in individual animals or populations post-vaccination
Detection and identification of the agent[a]						
Virus isolation	–	+	+++	+++	–	–
Antigen detection ELISA	–	–	+++	+++	–	–
CFT	–	–	+	+	–	–
LFD	–	–	+++	+++	–	–
Real-time RT-PCR	+	+	+++	+++	+	–
RT-PCR	+	+	+++	+++	+	–
Detection of immune response						
NSP Ab ELISA	+++	++	+++	+++	+++	–
SP Ab ELISA[b]	++	++	+++	+++	++	+++
VNT[b]	++	++	+++	+++	++	+++
AGID[b]	+	+	+	+	+	–

Key: +++ = recommended for this purpose; ++ recommended but has limitations;
+ = suitable in very limited circumstances; – = not appropriate for this purpose.
ELISA = enzyme linked immunosorbent assay; CFT = complement fixation test; LFD: lateral flow device; RT-PCR = reverse-transcriptase polymerase chain reaction; AGID = Agar gel immunodiffusion; NSP Ab ELISA = ELISA for antibodies against nonstructural proteins; SP Ab ELISA = ELISA for antibodies against structural proteins; VNT = Virus neutralisation test.
[a]It is essential to confirm the presence of FMDV following virus isolation by an antigen or nucleic acid detection test.
[b]The tests do not distinguish infected from vaccinated animals.

For laboratory diagnosis, the tissue of choice is epithelium or vesicular fluid. Ideally, at least 1 g of epithelial tissue should be collected from an unruptured or recently ruptured vesicle, usually from the tongue, buccal mucosa or feet. To avoid injury to personnel collecting the samples, as well as for animal welfare reasons, it is recommended that animals be sedated before any samples are obtained.

Epithelial samples should be placed in a transport medium composed of equal amounts of glycerol and 0.04 M phosphate buffer, pH 7.2–7.6, preferably with added antibiotics (penicillin [1000 International Units (IU)], neomycin sulphate [100 IU], polymyxin B sulphate [50 IU], mycostatin [100 IU]). If 0.04 M phosphate buffer is not available, tissue culture medium or phosphate-buffered saline (PBS) can be used instead, but it is important that the final pH of the glycerol/buffer mixture be in the range pH 7.2–7.6. FMDV is extremely labile in low pH and buffering of the transport media is critical for successful sample collection. Samples should be kept refrigerated or on ice until received by the laboratory.

Where epithelial tissue is not available from ruminant animals, for example in advanced or convalescent cases, or where infection is suspected in the absence of clinical signs, samples of OP fluid can be collected by means of a probang (sputum) cup (or in pigs by swabbing the throat) for submission to a laboratory for virus isolation or reverse-transcription polymerase chain reaction (RT-PCR). Viraemia may also be detected by examining serum samples by means of RT-PCR or virus isolation. For the collection of throat swabs from pigs, the animal should be held on its back in a wooden cradle with the neck extended. Holding a swab in a suitable instrument, such as an artery forceps, the swab is pushed to the back of the mouth and into the pharynx.

Before the collection of OP samples from cattle or large ruminants (e.g. buffalo), 2 ml transport fluid (composed of 0.08 M phosphate buffer containing 0.01% bovine serum albumin, 0.002% phenol red, antibiotics [1000 units/ml penicillin, 100 units/ml mycostatin, 100 units/ml neomycin, and 50 units/ml polymyxin], and adjusted to pH 7.2) should be added to a container of around 5 ml capacity capable of withstanding freezing above dry ice (solid carbon dioxide) or liquid nitrogen (Kitching & Donaldson, 1987).

An OP sample is collected by inserting a probang over the tongue into the oro-pharyngeal area and then passing it vigorously backwards and forwards 5–10 times between the first portion of the oesophagus and the back of the pharynx. The purpose is to collect oro-pharyngeal fluid and especially superficial epithelial cells from these areas, including the proximal part of the oesophagus, the walls of the pharynx, the tonsillar crypts and the surfaces of the soft palate. If the sample does not contain adequate cellular debris the actions may be repeated.

After collection of OP fluid by probang, the contents of the cup should be poured into a wide-necked transparent bottle of around 20 ml capacity. The fluid is examined, and should contain some visible cellular material. This fluid is then added to an approximately equal volume of transport fluid, ensuring that cellular material is transferred; the mixture is shaken gently and should have a final pH of around pH 7.6. Samples contaminated with ruminal contents may be unsuitable for culture. Samples seen to contain blood are not entirely satisfactory. Repeat sampling can be done after the mouth and throat of the animal have been rinsed with water or PBS. Where several animals are to be sampled, the probang must be cleaned and disinfected between each animal. This is done by washing the probang in tap water, immersing it in a suitable disinfectant (e.g. 0.5% [w/v] citric acid in tap water) and then rinsing off all the disinfectant with water before sampling the next animal.

OP samples from small ruminants are collected by putting 2 ml of transport fluid into a wide-necked bottle of about 20 ml capacity and, after collection, rinsing the probang cup in this transport fluid to discharge the OP sample. This is then transferred to a container of about 5 ml capacity for transport. The small container should be capable of withstanding freezing above dry ice or liquid nitrogen (Kitching & Donaldson, 1987).

Samples of OP fluid should be refrigerated or frozen immediately after collection. If they are to remain in transit for more than a few hours, they should preferably be frozen by being placed either above dry ice or liquid nitrogen. Before freezing, the containers should be carefully sealed using airtight screw caps or silicone. This is particularly important when using dry ice, as introduction of CO_2 into the OP sample will lower its pH, inactivating any FMDV that may be in the samples. Glass containers should not be used because there is a risk that they will explode on defrosting in the event of liquid nitrogen leaking into them. Samples should reach the laboratory in a frozen state or, if this is not feasible, maintained under reliable cold chain conditions during transit.

Special precautions are required when sending perishable suspect FMD material both within and between countries. The International Air Transport Association (IATA), Dangerous Goods Regulations (DGR) has explicit requirements for packaging and shipment of diagnostic specimens by all commercial means of transport. These are summarised in Chapter 1.1.2 *Collection, submission and storage off diagnostic specimens* and Chapter 1.1.3 *Transport of biological materials*. Forms and guidance on sample submission and specifications for manufacture of probang cups can be found on the website of the Pirbright WOAH Reference Laboratory at http://www.wrlfmd.org/. Procedures for collection and shipment of field samples for the diagnosis of vesicular diseases and its differential diagnosis can be found at the Pan-American FMD WOAH Reference Laboratory at http://www.panaftosa.org.br

1. Detection and identification of the agent

A range of sample types, including epithelium, OP samples, milk, serum and heart muscle from cases with myocarditis, may be examined by virus isolation or RT-PCR. By contrast, ELISA, CF and the lateral flow device LFD are suited to the examination of epithelial suspensions, vesicular fluids or cell culture supernatants, but are insufficiently sensitive for the direct examination of OP samples or serum. It is essential to confirm the presence of FMDV following virus isolation by an FMDV-specific antigen or nucleic acid detection test. A virus isolate or an RT-PCR product can be further characterised by sequencing.

1.1. Virus isolation

The epithelium sample should be taken from the PBS/glycerol, blotted dry on absorbent paper to reduce the glycerol content, which is toxic for cell cultures, and weighed. A suspension should be prepared by grinding the sample in sterile sand in a sterile pestle and mortar with a small volume of tissue culture medium and antibiotics. Further medium should be added until a final volume of nine times that of the epithelial sample has been added, giving a 10% suspension. This is clarified on a bench centrifuge at 2000 ***g*** for 10 minutes. Once clarified, such suspensions of field samples suspected to contain FMDV are inoculated onto cell cultures. Sensitive cell culture systems include primary bovine (calf) thyroid cells and primary pig, calf or lamb kidney cells. Established cell lines, such as BHK-21 (baby hamster kidney) and IB-RS-2 cells, may also be used but are generally less sensitive than primary cells for detecting low amounts of infectivity. The sensitivity of any cells used should be tested with standard preparations of FMDV. The use of IB-RS-2 cells aids the differentiation of swine vesicular disease virus (SVDV) from FMDV (as SVDV will only grow in cells of porcine origin) and is often essential for the isolation of porcinophilic strains, such as O Cathay. The cell cultures should be examined for cytopathic effect (CPE) for 48 hours. If no CPE is detected, the cells should be frozen and thawed, used to inoculate fresh cultures and examined for CPE for another 48 hours. In the case of OP fluids, pretreatment with an equal volume of chloro-fluoro-carbons may improve the rate of virus detection by releasing virus from immune complexes.

1.2. Immunological methods

1.2.1. Enzyme-linked immunosorbent assay

The preferred procedure for the detection of FMD viral antigen and identification of viral serotype is the ELISA (Ferris & Donaldson, 1992; Roeder & Le Blanc Smith, 1987). This is an indirect sandwich test in which different rows in multiwell plates are coated with rabbit antisera to each of the seven serotypes of FMDV. These are the 'capture' sera. Test sample suspensions are added to each of the rows, and appropriate controls are also included. Guinea-pig antisera to each of the serotypes of FMDV are added next, followed by rabbit anti-guinea-pig serum conjugated to an enzyme. Extensive washing is carried out between each stage to remove unbound reagents. A colour reaction on the addition of enzyme substrate and chromogen indicates a positive reaction. With strong positive reactions, this will be evident to the naked eye, but results can also be read spectrophotometrically at an appropriate wavelength. In this case, an absorbance reading greater than 0.1 above background indicates a positive reaction; the serotype of FMDV can also be identified. Values close to 0.1 should be confirmed by retesting or by amplification of the antigen by tissue culture passage and testing the supernatant once a CPE has developed. A suitable protocol is given below. Other protocols are available with slightly different formats and interpretation criteria (Alonso *et al*., 1993).

Depending on the species affected and the geographical origin of samples, it may be appropriate to simultaneously test for SVDV or vesicular stomatitis virus (VSV). Ideally a complete differential diagnosis should be undertaken in all vesicular conditions.

Rabbit antiserum to the 146S antigen of each of the seven serotypes of FMDV (plus SVDV or VSV if required) is used as a trapping antibody at a predetermined optimal concentration in carbonate/bicarbonate buffer, pH 9.6.

Control antigens are prepared from selected strains of each of the seven types of FMDV (plus SVDV or VSV if appropriate) grown on monolayer cultures of BHK-21 cells (IB-RS-2 cells for SVDV or VSV). The unpurified supernatants are used and pretitrated on ELISA plates. The final dilution chosen is that which gives an absorbance at the top of the linear region of the titration curve (optical density approximately 2.0), so that the five-fold dilutions of the control antigens used in the test give two additional lower optical density readings from which the titration curve can be derived. PBS containing 0.05% Tween 20 and phenol red indicator is used as a diluent (PBST).

Guinea-pig antisera prepared by inoculating guinea-pigs with 146S antigen of one of the seven serotypes of FMDV (plus SVDV if required) and preblocked with normal bovine serum (NBS) is used as the detecting antibody. Predetermined optimal concentrations are prepared in PBS containing 0.05% Tween 20, and 5% dried, nonfat skimmed milk (PBSTM).

Rabbit (or sheep) anti-guinea-pig immunoglobulin conjugated to horseradish peroxidase and preblocked with NBS is used at a predetermined optimum concentration in PBSTM. As an alternative to guinea-pig or rabbit antisera, suitable monoclonal antibodies (MAbs) can be used coated to the ELISA plates as capture antibody or peroxidase-conjugated as detecting antibody. A validated ready-to-use kit is available, based on pre-selected monoclonal antibodies, for detection and serotyping of six of the seven FMDV serotypes.

1.2.2. Test procedure

i) ELISA plates are coated with 50 µl/well rabbit antiviral sera in 0.05 M carbonate/bicarbonate buffer, pH 9.6. Rows A to H receive, respectively, antisera to serotypes O, A, C, SAT 1, SAT 2, SAT 3, Asia 1 and SVDV or VSV (optional). In countries from regions where SAT and Asia 1 serotypes have never circulated those serotypes are not routinely included.

ii) Leave overnight at 4°C in a stationary position or place on an orbital shaker set at 100–120 revolutions per minute in a 37°C incubator for 1 hour.

iii) Prepare test sample suspension (10% original sample suspension or undiluted clarified cell culture supernatant fluid).

iv) The ELISA plates are washed five times in PBS.

v) On each plate, load wells of columns 4, 8 and 12 with 50 µl PBST. Additionally, add 50 µl of PBST to wells 1, 2 and 3 of rows A to H on plate 1. To well 1 of row A of plate 1 add 12.5 µl of control antigen type O, to well 1 of row B add 12.5 µl of control antigen type A; continue in this manner for control antigen of types C, SAT 1, SAT 2, SAT 3, Asia 1 and SVDV or VSV (if appropriate) in order to well 1, rows C to H. Mix diluent in well 1 of rows A to H and transfer 12.5 µl from well 1 to 2 (rows A to H), mix and transfer 12.5 µl from well 2 to 3, mix and discard 12.5 µl from well 3 (rows A to H) (this gives a five-fold dilution series of each control antigen). It is only necessary to change pipette tips on the micropipette between antigens. The remainder of the plate can be loaded with the test sample(s). Add 50 µl of sample one to wells 5, 6 and 7 of rows A to H, the second sample is placed similarly in columns 9, 10 and 11, rows A to H.

   If more than two samples are to be tested at the same time, the other ELISA plates should be used as follows:

   Dispense 50 µl of the PBST to the wells (rows A to H) of columns 4, 8 and 12 (buffer control columns). Note that the control antigens are not required on these plates. These test samples may be added in 50 µl volumes in rows A to H to columns 1, 2, 3; 5, 6, 7; 9, 10, 11, respectively.

vi) Cover with lids and place on an orbital shaker at 37°C for 1 hour.

vii) Wash the plates by flooding with PBS – wash three times as before and empty residual wash fluid. Blot the plates dry.

viii) Transfer 50 µl volumes of each guinea-pig serum dilution to each plate well in the appropriate order, e.g. rows A to H receive, respectively, antisera to serotypes O, A, C, SAT 1, SAT 2, SAT 3, Asia 1 and SVDV or VSV (optional).

ix) Cover the plates with lids and replace on the orbital shaker. Incubate at 37°C for 1 hour.

x) The plates are washed again three times, and 50 µl of rabbit anti-guinea-pig immunoglobulin conjugated to horseradish peroxidase is added to each well. The plates are incubated at 37°C for 1 hour on a rotary shaker.

xi) The plates are washed again three times, and 50 µl of substrate solution, containing 0.05% % H_2O_2 plus orthophenylene diamine or a suitable alternative chromogen, is added to each well.

xii) The reaction is stopped after 15 minutes by the addition of 50 µl of 1.25 M sulphuric acid. The plates are read at 492 nm on a spectrophotometer linked to a computer.

1.2.3. Lateral flow device test

There are commercially available lateral flow devices (LFD) for the detection of FMDV antigens (Ferris *et al*., 2009), but WOAH has not yet received a validation dossier for these tests. As soon as a dossier is received, the manufacturer could apply for inclusion on the WOAH test register.

1.2.4. Complement fixation test

In general, the ELISA is preferable to the complement fixation test (CFT) because it is more sensitive and it is not affected by pro- or anti-complementary factors (Ferris & Dawson, 1988). If ELISA reagents are not available, or if subtyping is pursued, the CFT may be performed as follows:

The CF50% protocol in tubes used widely in South America for typing, subtyping and for establishing serological relationships (r values) is performed as follows: 0.2 ml antiserum to each FMDV serotype diluted at a predetermined optimal dilution in veronal buffer diluent (VBD) or borate-saline solution (BSS) is placed in separate tubes. To these, 0.2 ml of test sample suspension is added, followed by 0.2 ml of a complement dilution containing 4 units of complement. The test system is incubated at 37°C for 30 minutes prior to the addition of 0.4 ml 2% standardised sheep red blood cells (SRBC) in VBD or BSS sensitised with rabbit anti-SRBC. The reagents are incubated at 37°C for further 30 minutes and the tubes are subsequently centrifuged and read. Samples with less than 50% haemolysis are considered positive.

Other protocols performed in microplates are available and are performed as follows: antisera to each of the seven types of FMDV are diluted in VBD in 1.5-fold dilution steps from an initial 1/16 dilution to leave 25 µl of successive antiserum dilutions in U-shaped wells across a microtitre plate. To these are added 50 µl of 3 units of complement, followed by 25 µl of test sample suspension(s). The test system is incubated at 37°C for 1 hour prior to the addition of 25 µl of 1.4% SRBC in VBD sensitised with 5 units of rabbit anti-SRBC. The reagents are incubated at 37°C for a further 30 minutes and the plates are subsequently centrifuged and read. Appropriate controls for the test suspension(s), antisera, cells and complement are included. CF titres are expressed as the reciprocal of the serum dilution producing 50% haemolysis. A CF titre ≥36 is considered to be a positive reaction. Titre values of 24 should be confirmed by retesting an antigen that has been amplified through tissue culture passage.

1.3. Nucleic acid recognition methods

RT-PCR can be used to amplify genome fragments of FMDV in diagnostic materials including epithelium, milk, serum and OP samples. Real-time RT-PCR has a sensitivity comparable to that of virus isolation and automated procedures enhance sample throughput (Reid *et al.,* 2003). Serotyping primers have also been developed (Vangrysperre & De Clercq, 1996). Simplified RT-PCR systems for potential field-use are under development (Callahan *et al.,* 2002).

1.3.1. Agarose gel-based RT-PCR assay

A gel-based RT-PCR procedure is described (Reid *et al.,* 2000). The RT-PCR assay consists of the three successive procedures of (i) extraction of template RNA from the test or control sample followed by (ii) RT of the extracted RNA, (iii) PCR amplification of the RT product and (iv) detection of the PCR products by agarose gel electrophoresis.

1.3.2. Test procedure

i) Add 200 µl of test sample to 1 ml of RNA extraction reagent in a sterile tube. Store at –70°C until required for RNA extraction.

ii) Transfer 1 ml of the solution from i) into a fresh, sterile tube containing 200 µl of chloroform. Vortex mix for about 10–15 seconds and leave at room temperature for 3 minutes.

iii) Centrifuge for 15 minutes at 20,000 ***g***.

iv) Transfer 500 µl of the aqueous phase into a fresh, sterile tube containing 1 µl of glycogen (20 mg/ml) and add 500 µl of iso-propyl-alcohol (propan-2-ol). Vortex mix for a few seconds.

v) Leave at room temperature for 10 minutes then centrifuge for 10 minutes at 20,000 ***g***.

vi) Discard the supernatant fluid from each tube and add 1 ml of 70% ethanol. Vortex mix for a few seconds.

vii) Centrifuge for 10 minutes at 20,000 ***g***.

viii) Carefully remove the supernatant fluid from each tube taking care not to dislodge or lose any pellet at the bottom of the tube.

ix) Air dry each tube at room temperature for 2–3 minutes.

x) Resuspend each pellet by adding 20 µl of nuclease-free water to the tube.

xi) Keep the extracted RNA samples on ice if the RT step is about to be performed. Otherwise store at –70°C.

NOTE: As an alternative to phenol/chloroform, RNA extraction can be performed using commercially available kits based on chaotropic salt lysis and silica RNA affinity.

xii) For each sample to be assayed, add 2 µl of random hexamers (20 µg/ml) and 5 µl of nuclease-free water into a sterile 0.5 ml microcentrifuge tube. It is recommended to prepare the dilution in bulk for the total number of samples to be assayed but allowing for one extra sample.

xiii) Add 5 µl of RNA from the extraction procedure described above to give a volume of 12 µl in each tube. Mix by gently pipetting up and down.

xiv) Incubate at 70°C for 5 minutes.

xv) Cool at room temperature for 10 minutes.

xvi) During the 10-minute incubation period, prepare the RT reaction mixture described below for each sample. Prepare the reaction mixture in bulk in a sterile 1.5 ml microcentrifuge tube for the number of samples to be assayed plus one extra sample.

First strand buffer, 5× conc. (4 µl); bovine serum albumin (acetylated), 1 mg/ml (2 µl); dNTPs, 10 mM mixture each of dATP, dCTP, dGTP, dTTP (1 µl); DTT, 1 M (0.2 µl); Moloney Murine Reverse Transcriptase, 200 U/µl (1 µl).

xvii) Add 8 µl reaction mix to the 12 µl of random primer/RNA mix. Mix by gently pipetting.

xviii) Incubate at 37°C for 45 minutes.

xix) Keep the RT products on ice if the PCR amplification step is about to be performed, otherwise store at –20°C.

xx) Prepare the PCR mix described below for each sample. It is recommended to prepare the mix in bulk for the number of samples to be tested plus one extra sample.

Nuclease-free water (35 µl); PCR reaction buffer, 10× conc (5 µl); $MgCl_2$, 50 mM (1.5 µl); dNTPs, 10 mM mixture each of dATP, dCTP, dGTP, dTTP (1 µl); primer 1, 10 pmol/µl (1 µl); primer 2, 10 pmol/µl (1 µl); *Taq* Polymerase, 5 units/µl (0.5 µl).

xxi) Add 45 µl of PCR reaction mix to a well of a PCR plate or to a microcentifuge tube for each sample to be assayed followed by 5 µl of the RT product to give a final reaction volume of 50 µl.

xxii) Spin the plate or tubes for 1 minute in a suitable centrifuge to mix the contents of each well.

xxiii) Place the plate in a thermal cycler for PCR amplification and run the following programme:

94°C for 5 minutes: 1 cycle;
94°C for 1 minute, 55°C for 1 minute, 72°C for 2 minutes: 30 cycles;
72°C for 7 minutes: 1 cycle.

Times and temperatures may need to be optimised to the particular enzymes, reagents and PCR equipment used in individual laboratories.

xxiv) Mix a 20 µl aliquot of each PCR reaction product with 4 µl of staining solution and load onto a 1.5% agarose gel. After electrophoresis a positive result is indicated by the presence of a 328 bp band corresponding to FMDV sequence in the 5' untranslated region of the genome.

1.3.3. Stock solutions

i) Nuclease-free water, RNA extraction reagent, chloroform, glycogen, iso-propyl-alcohol (propan-2-ol), ethanol, random hexanucleotide primers, First strand buffer, BSA (acetylated), dNTPs, DTT, Moloney Murine Reverse Transcriptase, PCR reaction buffer (10×), $MgCl_2$ and *Taq* Polymerase are commercially available.

ii) Primers at a concentration of 10 pmol/µl: Primer 1 sequence 5'-GCCTG-GTCTT-TCCAG-GTCT-3' (positive strand); Primer 2 sequence 5'-CCAGT-CCCCT-TCTCA-GATC-3' (negative strand).

1.3.4. Real-time RT-PCR assay

The real-time RT-PCR assay can use the same procedures of extraction of total RNA from the test or control sample followed by RT of the extracted RNA as for the conventional agarose gel-based procedure. Automated extraction of total nucleic acid from samples followed by automated pipetting programmes for the RT and PCR steps (Reid *et al.,* 2003) can be used as an alternative to the manual procedures described above. PCR amplification of the RT product is performed by a different procedure. A more simple one-step method for combining the RT and PCR steps has also been described (Shaw *et al.,* 2007) and is widely used by laboratories. Detection of the PCR products in agarose gels is not required following real-time amplification.

i) Take the RT products from step xix (see above).

ii) Prepare the PCR mix described below for each sample. Again it is recommended to prepare the mix in bulk for the number of samples to be tested plus one extra sample: nuclease-free water (6 µl); PCR reaction master mix, 2× conc. (12.5 µl); real-time PCR forward primer, 10 pmol/µl (2.25 µl); real-time PCR reverse primer, 10 pmol/µl (2.25 µl); labelled probe, 5 pmol/µl (1 µl).

iii) Add 24 µl PCR reaction mix to a well of a real-time PCR plate for each sample to be assayed followed by 1 µl of the RT product to give a final reaction volume of 25 µl.

iv) Spin the plate for 1 minute in a suitable centrifuge to mix the contents of each well.

v) Place the plate in a real-time PCR machine for PCR amplification and run the following programme:

50°C for 2 minutes: 1 cycle;
95°C for 10 minutes: 1 cycle;
95°C for 15 seconds, 60°C for 1 minute: 50 cycles.

Times and temperatures may need to be optimised to the particular enzymes, reagents and PCR equipment used in individual laboratories.

vi) *Reading the results:* Assign a threshold cycle (CT) value to each PCR reaction from the amplification plots (a plot of the fluorescence signal versus cycle number; different cut-off values may be appropriate for different sample types; Parida *et al.,* 2007). The CT values used to assign samples as either FMDV positive or negative should be defined by individual laboratories using appropriate reference material. For example at the WOAH Reference Laboratory at Pirbright, negative test samples and negative controls should have a CT value at >50.0. Positive test samples and positive control samples should have a CT value <40. Samples with CT values falling within the range 40–50 are designated "borderline" and can be retested. Strong positive FMD samples have a CT value below 20.0 (Reid *et al.,* 2001).

1.3.5. Stock solutions for real-time PCR assay

i) Nuclease-free water and real-time PCR reaction master mixes are available from commercial suppliers.

ii) Either of the two following primers and probe sets can be used for real-time PCR of FMDV:

5'UTR (Reid *et al.,* 2001) Forward primer: CACYT-YAAGR-TGACA-YTGRT-ACTGG-TAC; Reverse primer: CAGAT-YCCRA-GTGWC-ICITG-TTA and labelled probe: CCTCG-GGGTA-CCTGA-AGGGC-ATCC.

3D (Callahan *et al.,* 2002) Forward primer: ACTGG-GTTTT-ACAAA-CCTGT-GA; Reverse primer: GCGAG-TCCTG-CCACG-GA and labelled probe: TCCTT-TGCAC-GCCGT-GGGAC.

1.3.6. Molecular epidemiology

The molecular epidemiology of FMD is based on the comparison of genetic differences between viruses. Dendrograms showing the genomic relationship between vaccine and field strains for all seven serotypes based on sequences derived from the 1D gene (encoding the VP1 viral protein) have been published (Knowles & Samuel, 2003; see also http://www.wrlfmd.org/). Comparison of whole genome sequences can provide further discrimination between closely related viruses and help to recreate the transmission pathways between farms within outbreaks (Cottam *et al.,* 2008). RT-PCR amplification of FMDV RNA, followed by nucleotide sequencing, is the current preferred option for generating the sequence data to perform these comparisons. Many laboratories have developed techniques for performing these studies, and reference laboratories hold databases containing over 6000 partial sequences.

The recommended method for VP1 analysis is to:

i) Extract FMDV RNA directly from epithelial suspensions or from a low cell culture passage.

ii) Perform an RT-PCR of the complete 1D gene (or if only part of the 1D gene, then the 3' end of the gene is more useful).

iii) Determine the nucleotide sequence of the PCR product (or at least 170 nucleotides [preferably 420 for the SAT types] at the 3' end of the gene).

A protocol complete with primer sequences, is available (Knowles *et al*., 2016) or can be downloaded from the following World Wide Web URLs:

http://www.wrlfmd.org/

http://bvs.panaftosa.org.br/

2. Serological tests

Serological tests for FMD are performed in support of four main purposes namely: 1) to certify individual animals prior to import or export (i.e. for trade); 2) to confirm suspected cases of FMD; 3) to substantiate absence of infection; 4) to demonstrate the efficacy of vaccination. For substantiating freedom from infection, different approaches are required according to whether the population has been vaccinated or not and if vaccination has been used, whether this has been applied as an emergency application or as part of an ongoing programme of vaccination. Different tests and different interpretations of test results will be appropriate according to the above-mentioned purposes and the validation of the selected procedure must take account of the purpose. For example, test cut-offs may be set at a different threshold for herd-based serosurveillance than is appropriate for certifying freedom from infection for individual animals for the purposes of international trade.

Serological tests for FMD are of two types; those that detect antibodies to viral structural proteins (SP) and those that detect antibodies to viral nonstructural proteins (NSPs).

The SP tests are relatively serotype-specific and detect antibodies elicited by vaccination and infection; examples are the virus neutralisation test (VNT) (Golding *et al*., 1976), the solid-phase competition ELISA (SPCE; Brocchi *et al*., 1990; Chenard *et al*., 2003; Mackay *et al*., 2001; Paiba *et al*., 2004) and the liquid-phase blocking ELISA (LPBE; Hamblin *et al*., 1986; 1987). These tests are highly sensitive, providing that the virus or antigen used in the test is closely matched to the strain circulating in the field. They are the tests used to certify animals prior to movement, including for international trade purposes and are appropriate for confirming previous or ongoing infection in nonvaccinated animals as well as for monitoring the immunity conferred by vaccination in the field. The VNT requires cell culture facilities, the use of live virus and takes 2–3 days to provide results. The ELISAs are blocking- or competition-based assays that use serotype-specific polyclonal antibodies (PAbs) or MAbs, are quicker to perform and are not dependent on tissue culture systems and the use of live viruses. Low titre false-positive

reactions can be expected in a small proportion of the sera in either ELISA formats. An approach combining screening by ELISA and confirming the positives by the VNT minimises the occurrence of false-positive results. Reference sera to standardise FMD SP serological tests for some serotypes and subtypes are available from the WOAH Reference Laboratory at Pirbright.

The detection of antibody to the NSPs of FMDV can be used to identify past or present infection with any of the seven serotypes of the virus, whether or not the animal has also been vaccinated. Therefore the tests can be used to confirm suspected cases of FMD and to evaluate prevalence of infection or to substantiate freedom from infection on a population basis. For certifying animals for trade, the tests have the advantage over SP methods that the serotype of virus does not have to be known. However, there is experimental evidence that some cattle, vaccinated and subsequently challenged with live virus and confirmed persistently infected, may not be detected in some anti-NSP tests, causing false-negative results (Brocchi *et al*., 2006). These assays measure antibody to NSPs using antigens produced by recombinant techniques in a variety of *in-vitro* expression systems. Antibody to the polyproteins 3AB or 3ABC are generally considered to be the most reliable indicators of infection (Mackay *et al*., 1997). In animals seropositive for antibody to 3AB or 3ABC, antibody to one or more of the other NSPs can aid in the final interpretation of the test (Bergmann *et al*., 2000; Mackay *et al*., 1997). However, lack of vaccine purity may affect diagnostic specificity as the presence of NSPs in some vaccine preparations may result in misclassification in animals that have been repeatedly vaccinated. Procedures for evaluating vaccine purity are covered in Section D of this chapter.

International standard sera for testing of cattle have been developed and are available from the WOAH Reference Laboratories in Brazil and UK (Campos *et al*., 2008). In the future, standard sera will also be made available for sheep and pigs. Bovine serum panels have also been established to compare the sensitivity of NSP tests (Parida *et al*., 2007).

2.1. Virus neutralisation test

The quantitative VN microtest for FMDV antibody is performed with IB-RS-2, BHK-21, lamb or pig kidney cells in flat-bottomed tissue-culture grade microtitre plates.

Stock virus is grown in cell monolayers and stored at –20°C after the addition of 50% glycerol. (Virus has been found to be stable under these conditions for at least 1 year.) The sera are inactivated at 56°C for 30 minutes before testing. The control standard serum is 21-day convalescent or post-vaccination serum. A suitable medium is Eagle's complete medium/LYH (Hank's balanced salt solution with yeast lactalbumin hydrolysate) with HEPES buffer and antibiotics.

The test is an equal volume test in 50 µl amounts.

2.1.1. Test procedure

i) Starting from a 1/4 dilution, sera are diluted in a twofold, dilution series across the plate, using at least two rows of wells per serum, preferably four rows, and a volume of 50 µl.

ii) Previously titrated virus is added; each 50 µl unit volume of virus suspension should contain about 100 $TCID_{50}$ (50% tissue culture infective dose) within an accepted range (e.g. 32–320 $TCID_{50}$).

iii) Controls include a standard antiserum of known titre, a cell control, a medium control, and a virus titration used to calculate the actual virus titre used in the test.

iv) Incubate at 37°C for 1 hour with the plates covered.

v) A cell suspension at 10^6 cells/ml is made up in medium containing 10% bovine serum (specific antibody negative) for cell growth. A volume of 50 µl of cell suspension is added to each well.

vi) Plates are sealed with pressure-sensitive tape and incubated at 37°C for 2–3 days. Alternatively, the plates may be covered with loosely fitting lids and incubated in an atmosphere of 3–5% carbon dioxide at 37°C for 2–3 days.

vii) Microscope readings may be feasible after 48 hours. The plates are finally fixed and stained routinely on the third day. Fixation is effected with 10% formol/saline for 30 minutes. For staining, the plates are immersed in 0.05% methylene blue in 10% formalin for 30 minutes.

An alternative fixative/stain solution is naphthalene blue black solution (0.4% [w/v] naphthalene blue black, 8% [w/v] citric acid in saline). The plates are rinsed in tap water.

viii) Positive wells (where the virus has been neutralised and the cells remain intact) are seen to contain blue-stained cells sheets; the negative wells (where virus has not been neutralised) are empty. Titres are expressed as the final dilution of serum present in the serum/virus mixture where 50% of wells are protected (Kärber, 1931). The test is considered to be valid when the amount of virus used per well is in the range $\log_{10}$ 1.5–2.5 $TCID_{50}$, and the positive standard serum is within twofold of its expected titre.

ix) Interpretation of tests can vary between laboratories in regard to the negative/positive cut-off threshold. Laboratories should establish their own criteria by reference to standard reagents that can be obtained from the WOAH Reference Laboratory at Pirbright. In general, a titre of 1/45 or more of the final serum dilution in the serum/virus mixture is regarded as positive. A titre of less than 1/16 is considered to be negative. For certification of individual animals for the purposes of international trade, titres of 1/16 to 1/32 are considered to be doubtful, and further serum samples may be requested for testing; results are considered to be positive if the second sample has a titre of 1/16 or greater. For the purposes of herd-based serosurveillance as part of a statistically valid serological survey, a cut-off of 1/45 may be appropriate. Cut-off titres for evaluating immunological protection afforded by vaccination have to be established from experience of potency test results with the relevant vaccine and target species.

2.2. Solid-phase competition enzyme-linked immunosorbent assay

The method described (Paiba *et al.,* 2004) can be used for the detection of antibodies against each of the seven serotypes of FMDV. As an alternative to guinea-pig or rabbit antisera, suitable MAbs can be used coated to the ELISA plates as capture antibody or peroxidase-conjugated as detecting antibody (Brocchi *et al.,* 1990). Commercial kits based on monoclonal antibodies are available for serotype O (Chenard *et al.,* 2003), serotype A, serotype Asia 1 and serotype SAT 2 with a different format but similar performance characteristics.

Rabbit antiserum to the 146S antigen of one of the seven types of FMDV is used as the trapping antibody at a predetermined optimal concentration in carbonate/bicarbonate buffer, pH 9.6.

Antigens are prepared by inactivating viruses propagated in cell culture with ethyleneimine using the procedures described for vaccine manufacture. The final dilution chosen is that which, after addition of an equal volume of diluent, gives an absorbance on the upper part of the linear region of the titration curve (optical density approximately 1.5). PBS containing 0.05% Tween 20, 10% NBS and 5% normal rabbit serum and phenol red indicator is used as a diluent (blocking buffer).

Guinea-pig antisera, prepared by inoculating guinea-pigs with 146S antigen of one of the seven serotypes and preblocking with NBS, is used as the detecting antibody. Predetermined optimal concentrations are prepared in blocking buffer PBS containing 0.05% Tween 20, and 5% dried, nonfat skimmed milk (PBSTM).

Rabbit (or sheep) anti-guinea-pig immunoglobulin conjugated to horseradish peroxidase and preblocked with NBS is used as conjugate at a predetermined optimum concentration in PBSTM blocking buffer.

Test sera are diluted in PBST blocking buffer.

The solid-phase competitive ELISA is more specific but as sensitive as the liquid-phase blocking ELISA (Mackay *et al.,* 2001; Paiba *et al.,* 2004). Methods have been described for the development of secondary and working standard sera (Goris & De Clercq, 2005a) and for charting assay performance (Goris & De Clercq, 2005b).

2.2.1. Test procedure

i) ELISA plates are coated with 50 µl/well rabbit antiserum homologous to the antigen being used, diluted in carbonate/bicarbonate buffer, pH 9.6, and left overnight in a humid chamber at 4°C.

ii) The ELISA plates are washed three times with PBS.

iii) Then 50 µl of the FMDV antigen diluted in blocking buffer is added to each well of the ELISA plates. (Blocking buffer: 0.05% [w/v] Tween 20, 10% [v/v] NBS, 5% [v/v] normal rabbit serum.) The plates are covered and placed on an orbital shaker at 37°C for 1 hour, with continuous shaking.

iv) After washing three times with PBS, 40 µl of blocking buffer is added to each well, followed by 10 µl of test sera (or control sera), giving an initial serum dilution of 1/5.

v) Immediately 50 µl of guinea-pig anti-FMDV antiserum diluted in blocking buffer is added, giving a final serum dilution of 1/10.

vi) The plates are covered and incubated on an orbital shaker at 37°C for 1 hour.

vii) After washing three times with PBS, 50 µl of anti-guinea-pig Immunoglobulin conjugate (preblocked by incubation for 1 hour at room temperature with an equal volume of NBS) diluted in blocking buffer is added. The plates are covered and incubated for 1 hour at 37°C on an orbital shaker.

viii) After washing three times with PBS, 50 µl of substrate solution, containing 0.05% H_2O_2 plus orthophenylene diamine or a suitable alternative chromogen, is added to each well.

ix) The reaction is stopped after 10 minutes by the addition of 50 µl of 1 M sulphuric acid. The plates are read at 492 nm on a spectrophotometer linked to a computer.

x) *Controls:* On each plate two wells are used for conjugate control (no guinea-pig serum), four wells each for strong and weak positive sera, two wells for negative sera, and four wells for 0% competition (no test sera).

xi) *Interpretation of the results:* A percentage of inhibition is calculated for each well, either manually or using a suitable computer programme (100 – [optical density of each test or control value/mean optical density of the 0% competition] × 100%), representing the competition between the test sera and the guinea-pig anti-FMDV antisera for the FMDV antigen on the ELISA plate. Laboratories should validate the assay in terms of the cut-off value above which sera should be considered positive in relation to (i) the particular serotypes and strains of virus under investigation (ii) the purpose of testing (iii) the population under test, using the methods described in Chapter 1.1.6 *Validation of diagnostic assays for infectious diseases of terrestrial animals*. At the WOAH Reference Laboratory at Pirbright, for serotype O, for all species, for the purposes of demonstrating freedom from infection in a naïve population, greater than 60% inhibition is considered positive (Paiba *et al.,* 2004). For maximum sensitivity, for example when certifying individual animals for international trade, an inconclusive range may be set between 40 and 60%.

2.3. Liquid-phase blocking enzyme-linked immunosorbent assay

Antigens are prepared from selected strains of FMDV grown on monolayers of BHK-21 cells. The unpurified supernatants are used and pretitrated in a twofold dilution series but without serum. The final dilution chosen is that which, after addition of an equal volume of diluent (see below), gives an absorbance on the upper part of the linear region of the titration curve (optical density approximately 1.5). PBS containing 0.05% Tween 20 and phenol red indicator is used as a diluent (PBST). The other reagents used in the test are the same as those in the solid-phase blocking ELISA. An example of the test procedure is described below. Temperature and incubation times can vary depending on the protocol.

2.3.1. Test procedure

i) ELISA plates are coated with 50 µl/well rabbit antiserum homologous to the antigen being used and left overnight in a humid chamber at room temperature.

ii) The ELISA plates are washed three times with PBS.

iii) In U-bottomed multiwell plates (carrier plates) 50 µl of a duplicate, twofold series of each test serum is prepared, starting at 1/8. To each well, 50 µl of a constant dose of viral antigen that is homologous to the rabbit antisera used to coat the plates is added and the mixtures are left overnight at 4°C, or incubated at 37°C for 1 hour. The addition of the antigen increases the final serum dilution to 1/16.

iv) Then 50 µl of serum/antigen mixtures is transferred from the carrier plates to the rabbit-serum coated ELISA plates and the plates are incubated at 37°C for 1 hour on a rotary shaker.

v) After washing, 50 µl of guinea-pig antiserum homologous to the viral antigen used in the previous step (iv) (preblocked with NBS and diluted in PBST containing 5% skimmed milk powder) is added to each well. The plates are then incubated at 37°C for 1 hour on a rotary shaker.

vi) The plates are washed and 50 µl of rabbit anti-guinea-pig immunoglobulin conjugated to horseradish peroxidase (preblocked with NBS and diluted in PBST containing 5% skimmed milk powder) is added to each well. The plates are incubated at 37°C for 1 hour on a rotary shaker.

vii) The plates are washed again three times and 50 µl of substrate solution, containing 0.05% H_2O_2 plus orthophenylene diamine or a suitable alternative chromogen, is added to each well.

viii) The reaction is stopped after 15 minutes by the addition of 50 µl of 1 M sulphuric acid. The plates are read at 492 nm on a spectrophotometer linked to a computer.

ix) Controls: A minimum of four wells each of strong positive, weak positive and negative bovine reference sera at a final dilution of 1/32 should be included on each plate together with an equivalent number of reaction (antigen) control wells containing antigen in diluent alone without serum. For end-point titration tests, duplicate twofold dilution series of positive and negative homologous bovine reference sera should be included on at least one plate of every run.

x) *Interpretation of the results:* Antibody titres are expressed as the 50% end-point titre, i.e. the dilution at which the reaction of the test sera results in an optical density equal to 50% inhibition of the median optical density of the reaction (antigen) control wells (Kärber, 1931). The median is calculated as the mean of two mid-values of the reaction control wells, eliminating from the calculation the highest and lowest values (alternatively, the mean value can be used after setting suitable tolerance limits to control for inter-well variation). In general sera with titres greater than or equal to 1/90 are considered to be positive. A titre of less than 1/40 is considered to be negative. For certification of individual animals for the purposes of international trade, titres of greater than 1/40, but less than 1/90 are considered to be doubtful, and further serum samples may be requested for testing; results are considered to be positive if the second sample has a titre of 1/40 or greater. For the purposes of herd-based serosurveillance as part of a statistically valid serological survey, a cut-off of 1/90 may be appropriate. Cut-off titres for evaluating immunological protection afforded by vaccination have to be established from experience of potency test results with the relevant vaccine and target species.

2.4. Nonstructural protein (NSP) antibody tests

Antibody to expressed recombinant FMDV NSPs (e.g. 3A, 3B, 2B, 2C, 3ABC) can be measured by different ELISA formats or immunoblotting. These ELISAs either use purified antigens absorbed directly to microplates or use PAbs or MAbs to trap specific antigens from semi-purified preparations (Bergmann *et al*., 2000; De Diego *et al*., 1997; Mackay *et al*., 1997; Sorensen *et al*., 1998). The screening method used in Panaftosa is described in detail below. Other indirect and competitive ELISAs detecting bovine antibodies to 3ABC have been shown to have equivalent diagnostic performance characteristics (Brocchi *et al*., 2006). This same study corroborates preliminary data from Panaftosa that suggests that the diagnostic performance characteristics of these tests are similar in cattle, sheep and pigs. Commercial kits validated for identification of antibodies against FMDV NSPs in cattle and other species are also available.

2.4.1. Indirect enzyme-linked immunosorbent assay

2.4.1.1. Preparation of recombinant antigens

See Section B.2.4.2. *Enzyme-linked immunoelectrotransfer blot assay*.

2.1.1.2. Test procedure

i) Microplates are coated overnight at 4°C with 1 µg/ml of the fusion antigen 3ABC in carbonate/ bicarbonate buffer, pH 9.6 (100 µl per well). Antigen 3ABC was expressed and purified as indicated for the EITB (enzyme-linked immunoelectrotransfer blot) tests (Neizert *et al.,* 1991).

ii) The plates are washed six times with PBS, pH 7.2, supplemented with 0.05% Tween 20 (PBST).

iii) Test sera (100 µl per well) are added in a 1/20 dilution in blocking buffer consisting of PBS, 0.05% Tween 20, 5% nonfat dry milk, 10% equine sera and 0.1% *Escherichia coli* lysate. Each plate includes a set of strong and weak positive and negative controls calibrated against the International Standard Sera described below.

iv) The plates are incubated for 30 minutes at 37°C and washed six times in PBST.

v) Horseradish-peroxidase-conjugated rabbit anti-species IgG is diluted optimally in the blocking buffer, added at 100 µl per well and the plates are incubated for 30 minutes at 37°C.

vi) After six washings, each well is filled with 100 µl of 3'3', 5'5'-tetramethylbenzidine plus 0.004% (w/v) H_2O_2 in phosphate/citrate buffer, pH 5.5.

vii) The reaction is stopped after 15 minutes of incubation at room temperature by adding 100 µl of 0.5 M H_2SO_4. Absorbance is read at 450 nm and at 620 nm for background correction.

viii) *Interpreting the results:* Test results are expressed as per cent positivity relative to the strong positive control [(optical density of test or control wells/optical density of strong positive control) × 100] or alternatively as a test to control (T/C) index relative to a cut-off (i.e. threshold positive) control. Profiling the NSP antibody reactivity levels in herds along with age/vaccination stratification aids interpretation of herd infection status in vaccinated populations (Bergmann *et al.,* 2003). Test cut-off values, with or without suspicious zones, need to be determined with consideration to the purpose of testing and the intended target population. Inconclusive results may be followed up using confirmatory tests, retesting with EITB or a second NSP ELISA (taking account of the conditional dependence of the two tests). The overall test system sensitivity and specificity must be taken into account when designing the serosurveillance programme. Although not a suitable test for certifying animals prior to movement, NSP ELISAs may be a valuable adjunct in circumstances where the serotype or subtype of virus in the originating country is not known.

2.4.2. Enzyme-linked immunoelectrotransfer blot assay (EITB)

The EITB assay has been widely applied in South America as a confirmatory test for the above-described screening method. Further information is available from the WOAH Reference Laboratory, Panaftosa, PAHO/WHO.

2.4.2.1. Preparation of test strips containing the recombinant antigens

i) The five bioengineered FMDV NSPs 3A, 3B, 2C, 3D and 3ABC are expressed in *E. coli* C600 by thermo-induction. The 3D polypeptide is expressed in its complete form (McCullough *et al.,* 1992) whereas the rest of the proteins are obtained as fusions to the N-terminal part of the MS-2 polymerase gene (Strebel *et al.,* 1986).

ii) The expressed polymerase is purified over phosphocellulose, followed by poly(U) Sepharose columns. The fused proteins 3A, 3B, 2C and 3ABC are purified by sequential extraction of the bacterial extracts with increasing concentrations of urea. The 7M fraction containing the fusion proteins is further purified on a preparative 10% SDS-PAGE (sodium dodecyl sulphate-polyacrylamide gel electrophoresis). The fusion protein band is excised from the gel and electroeluted (McCullough *et al.,* 1992).

iii) A mixture containing 20 ng/ml of each one of the purified recombinant polypeptides is separated on 12.5% SDS-PAGE and electrophoretically transferred to nitrocellulose (McCullough *et al.,* 1992).

2.4.2.2. Test procedure

i) The required amount of test strips should be assessed, taking into account that for each nitrocellulose sheet, which defines one transferred gel, a positive, a weakly positive, a cut-off and a negative control serum should be assayed. In general, 24 nitrocellulose strips, each 3 mm wide, should result from a gel.

ii) A volume of 0.8 ml of saturation buffer (50 mM Tris/HCl, pH 7.5; 150 mM NaCl; 0.2% Tween 20; 5% nonfat dry milk; and 0.05% bacterial *E. coli* lysate) is added to each well. The antigen-coated strips are blocked by placing the trays on a rocker and agitating for 30 minutes at room temperature (20–22°C).

iii) A dilution of 1/200 of test sera and of each of the controls is added to the appropriate trough. The strips must be completely submerged and facing upwards, and maintained in that position during the whole process.

iv) Strips are incubated for 60 minutes on a rocker at room temperature.

v) Liquid is removed from the trays, and each test strip is washed three times with washing solution (50 mM Tris/HCl, pH 7.5; 150 mM NaCl; and 0.2% Tween 20) by agitation for 5 minutes.

vi) The alkaline-phosphatase-conjugated rabbit anti-bovine solution is added to each test well, and the strips are incubated with shaking for 60 minutes at room temperature.

vii) The liquid is removed from the trays and each test strip is washed three times with washing solution as above.

viii) Substrate solution (0.015% bromochloroindolylphosphate/0.03% nitroblue tetrazolium) is prepared in substrate buffer (100 mM NaCl; 5 mM $MgCl_2$; and 100 mM Tris/HCl, pH 9.3), and is added to each test well.

ix) Strips are incubated by placing the test tray on the orbital mixer and agitating until the cut-off control shows five distinct, discernible bands. Strips are washed with running deionised water and air-dried.

x) *Interpreting the results:* The EITB may be scanned with a densitometer but visual reading, although more subjective, is considered suitable as well. Individual control sera are tested that exhibit minimal but consistent staining for each of the five antigens. A test sample is considered positive if antigens 3ABC, 3A, 3B and 3D (±2C) demonstrate staining densities equal to or higher than that of their appropriate controls. A sample is considered negative if two or more antigens demonstrate densities below their control sera. Test samples not fitting either profile are considered indeterminate.

C. REQUIREMENTS FOR VACCINES

The control of FMD is a national and regional responsibility and, in many countries, the vaccine may be used only under the control of the Veterinary Authority.

Guidelines for the production of veterinary vaccines are given in Chapter 1.1.8 *Principles of veterinary vaccine production*. The guidelines given here and in chapter 1.1.8 are intended to be general in nature and may be supplemented by national and regional requirements. Varying requirements relating to quality, safety and efficacy apply in particular countries or regions in order for manufacturers to obtain an authorisation or licence for a veterinary vaccine. Where possible, manufacturers should seek to obtain such a license or authorisation for their FMD vaccines as independent verification of the quality of their product.

FMD vaccine production facilities should operate under appropriate biosecurity and containment procedures and practices as outlined in Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities.*

Routine vaccination against FMD is used in many countries or zones recognised as free from foot and mouth disease with vaccination and in countries where the disease is endemic. In contrast, a number of disease-free countries have never vaccinated their livestock but have preferred the use of strict movement controls and culling of infected and contact animals when outbreaks have occurred. Nevertheless, many disease-free countries

maintain the option to vaccinate and have their own strategic reserves of highly concentrated inactivated virus preparations. Such antigen reserves offer the potential of supplying formulated vaccine in an 'emergency' at short notice. (See also Chapter 1.1.10 *Vaccine banks*.)

Traditional FMD vaccines may be defined as a fixed formulation containing defined amounts (limits) of one or more chemically inactivated cell-culture-derived preparations of a seed virus strain blended with a suitable adjuvant/s and excipients. See chapter 1.1.8 for biotechnology-derived vaccines such as recombinant or peptide vaccines.

Antigen banks may be defined as stockpiles of antigen components, registered or licensed according to the finished vaccine, and which can be stored under ultra-low temperatures for a long time for subsequent formulation into vaccine as and when required.

The vaccines are formulated for their specific purpose and in the case of vaccines destined for use in cattle, both aluminium hydroxide saponin adjuvanted and oil adjuvanted vaccines may be used. For use in swine, double oil emulsions are preferred due to their efficacy.

FMD vaccines may be classified as either 'standard' or 'higher' potency vaccines. Standard potency vaccines are formulated to contain sufficient antigen and appropriate adjuvant to ensure that they meet the minimum potency level required (recommended 3 PD_{50} [50% protective dose]; 75% EPP (expected percentage of protection) or 12 protected out of 16 vaccinated and challenged in PGP [protection against generalised foot infection] test) for the duration of the shelf life claimed by the manufacturer. This kind of vaccine is usually suitable for use in routine vaccination campaigns. For vaccination in naïve populations to control FMD outbreaks, higher potency vaccines (e.g.> 6 PD_{50} for the duration of the shelf life claimed by the manufacturer) are recommended for their wider spectrum of immunity as well as their rapid onset of protection.

Because of the presence of multiple serotypes of the virus, it is common practice to prepare vaccines from two or more different virus serotypes. In certain areas, it may be advisable to include more than one virus strain per serotype to ensure broad antigenic coverage against prevailing viruses.

1. Seed virus management

1.1. Characteristics of the seed virus

Selection of master seed viruses (MSVs) should ideally be based on their ease of growth in cell culture, virus yield, antigenic stability at industrial level and broad antigenic spectrum. Isolates to prepare MSVs should be characterised and distributed, preferably by WOAH FMD Reference laboratories; they should be selected in accordance with the regional epidemiological importance of each strain.

The exact source of the isolate should be recorded and should include details such as the location, species and the type of material from which the virus was derived. Unique nomenclature should be used to identify the FMDV strain. The *in-vitro* passage history of the virus and details of the ingredients should be recorded in accordance with chapter 1.1.8. The passage level of the seed virus should be kept to a minimum to avoid antigenic or genetic changes.

1.2. Method of culture

Methods of culture shall comply with the chapter 1.1.8. Where no suitable established vaccine strain exists, new vaccine strains are derived through the establishment of MSVs from local field isolates by adapting them to growth in suspension or monolayer cells by serial passages. In order to remove the risk of contaminating lipid-enveloped viruses, it is recommended that putative MSVs undergo a validated organic solvent treatment prior to, or during, adaptation.

1.3. Validation as a vaccine strain

MSVs must be, antigenic and genetically well characterised and proven to be pure and free from extraneous agents in accordance with Chapter 1.1.9 *Tests for sterility and freedom from contamination of biological materials intended for veterinary use* and those listed by the appropriate licensing authorities. Homology should be established with the original candidate isolates and effectiveness against the circulating strains from which they were developed should be proven. This often

encompasses a number of methods, the most reliable being *in-vivo* protection assays. Alternatively, *in-vitro* tests (preferably virus neutralisation) can also be used, which require the availability of post-vaccination sera against these master seeds (see Section D of this chapter).

Seed viruses may be stored at low temperature (e.g. –70°C) or freeze-dried. Working seed viruses may be expanded in one or a few more passages from the master seed stock and used to infect the final cell culture.

Consideration should also be given to minimising the risk of transmission of transmissible spongiform encephalopathy agents (TSEs) by ensuring that TSE risk materials are not used as the source of the virus or in any of the media used in virus propagation.

1.4. Emergency procedures for provisional acceptance of new MSV, and subsequent release of formulated vaccines

In the case of incursion in a region of a new strain to which protection is not elicited by existing vaccine strains, it may be necessary to develop a new vaccine strain from a representative field isolate. Before the new MSV can be accepted, full compliance should be demonstrated with the relevant guidelines to demonstrate freedom from all extraneous agents listed by the appropriate licensing authorities using both general and specific tests, and to establish homology to the original candidate isolates. The time taken to raise the specific antisera necessary to neutralise the new strain for use in the general tests for detection of extraneous agents and to conduct other specific tests that require specialised techniques may be lengthy. Therefore, in emergency situations where there is insufficient time to complete full testing of the MSV, provisional acceptance of the new strain should be based on a risk analysis of the possibility of contamination of the antigen produced from the new MSV with extraneous agents. This risk assessment should take into account that the virus is inactivated using a chemical inactivant with first order kinetics. Further assurance is provided by the requirement for the kinetics of inactivation to be monitored and recorded for each production batch.

2. Method of manufacture

The recommended method of virus propagation for antigen production is the growth of FMDV in large-scale suspension cultures or monolayers using cell lines under sterile conditions.

A suitable strain of the virus is used to infect a suspension or monolayers of an established cell line, such as BHK-21. Such cell cultures should be proven to be free from contaminating microorganisms.

When the virus is expected to have reached its maximum yield, the culture is clarified, often by centrifugation and/or filtration. The virus is subsequently inactivated by addition of an inactivant of first order, usually ethyleneimine (EI) in the form of binary ethyleneimine (BEI) (Bahnemann, 1990). It is important that the necessary safety precautions for working with BEI/EI are fully observed. The BEI is added to a virus suspension, to give a predetermined final concentration. Inactivation must be duly validated and documented to show the inactivation kinetic and the results of the inactivation controls. The time period for BEI treatment and temperature used for inactivation must be validated for the actual conditions and equipment used. To decrease the likelihood of live virus failing to contact the inactivant, e.g. BEI/EI, it is essential to transfer the vessel contents immediately to a second sterile vessel where inactivation is allowed to go to completion according to the validated inactivation kinetic and taking into account possible regulatory requirements for additional waiting times.

During inactivation, the virus titre is monitored by a sensitive and reproducible technique. After inactivation any residual BEI/EI in the harvest should be neutralised, for example by adding excess sodium thiosulphate solution to a final concentration of 2%.

The inactivated virus is concentrated by ultrafiltration. Concentrated inactivated virus may be purified further by procedures such as chromatography. These concentrated and purified antigens can be formulated into vaccines or stored at low temperatures for many years, and made into vaccine when required by dilution in a suitable buffer and addition of adjuvants (Doel & Pullen, 1990).

Conventional FMD vaccines are usually formulated as oil adjuvanted or aqueous. Oil-adjuvanted vaccines are usually formulated as water-in-oil emulsion using mineral oils. The mineral oil is usually premixed with an emulsifying agent before the addition of a proportion, or all, of the aqueous phase of the vaccine, and emulsified by

use of a colloid mill or continuous mechanical or flow ultrasonic emulsifier. More complex double emulsions (water/oil/water) may be produced by emulsifying once more in an aqueous phase containing a small amount of detergent such as Tween 80. Ready-to-use oil adjuvants are now available commercially for different types of emulsion.

Aqueous vaccine is prepared by adsorbing the virus on to aluminium hydroxide gel, one of the adjuvant constituents of the final vaccine blend. The final blend of the vaccine may include other components, such as antifoam, lactalbumin hydrolysate, tryptose phosphate broth, amino acids, vitamins, buffer salts and other substances. An adjuvant such as saponin is also usually incorporated, as well as preservatives.

When using novel components, including adjuvants or preservatives, in any vaccine it is important to take into account that its status, with regard to residues in products derived from food-producing species, must be assessed to ensure that adequate assurance can be giving to licensing authorities in relation to safety for consumers. This requirement limits considerably the choice of adjuvants and preservatives for use in food-producing species.

3. In-process control

In general, virus titres reach optimum levels between 18 and 24 hours of the cell culture being infected, depending on the serotype. The time chosen to harvest the culture may be based on a number of assays; for instance cell death. Virus concentration may be assessed by an infectivity test, sucrose or CsCl density gradient or serological techniques. It is preferable to use more than one method as they may complement one another.

3.1. Inactivation kinetics

During inactivation of the virus, timed samples should be taken at regular intervals for the purpose of monitoring the rate and linearity of the inactivation process. Virus titres in the samples are determined by inoculation of cell cultures proven to be highly susceptible to FMDV, e.g. BHK. Such cultures permit the testing of statistically meaningful samples under reproducible conditions. The $\log_{10}$ infectivity of the timed samples are plotted against time, and the inactivation procedure is not considered to be satisfactory unless at least the latter part of the slope of the line is linear and extrapolation indicates that there would be less than one infectious particle per 10^4 litres of liquid preparation at the end of the inactivation period.

3.2. Inactivation control

The test for innocuity is an in-process test that should be carried out for every batch of antigen. Cells used to test for absence of residual live virus should undergo a sensitivity test to prove that they are suitable for virus replication. Following inactivation, a sample of each batch of inactivated antigen representing at least 200 doses of vaccine antigen should be tested for freedom from infectious virus by inoculation of sensitive monolayer cell cultures, preferably of the same origin as those used for the production of antigen. It may be necessary to concentrate the antigen to do this, in which case it must be shown that the concentrated material does not interfere with the sensitivity or reading of the assay. The cell sheets are examined daily over a period of 2–3 days, after which the spent medium is transferred to fresh monolayers and the original monolayers are replenished with fresh medium. Using this method, traces of live virus can be amplified by the passage procedure and detected on the basis of CPE observed. Three passages of the original virus preparation are commonly used. A variant on this method is to freeze–thaw the old monolayers to release intracellular virus, which can be detected by further passage.

4. Final product batch tests

4.1. Innocuity testing

The bulk inactivated antigen and the final formulated product should undergo innocuity test to prove absence of infectious virus. In the final product, antigen must be extracted from adjuvant following an appropriate validated method. A sample representing at least 200 doses of vaccine (including all product presentations) must be used for testing for freedom of infectious virus by inoculation of sensitive cell culture monolayers. After elution, antigen may be concentrated for inoculation in cell monolayers. Test procedure is as described in Section C.3.2 *Inactivation control*.

4.2. Sterility testing

The bulk inactivated antigen, concentrated antigen and the final formulated product should undergo sterility testing. Guidelines on techniques and culture media, which allow the detection of a wide range of organisms, are described in Chapter 1.1.9.

4.3. Identity testing

The bulk inactivated antigen, concentrated antigen and the final formulated product should undergo identity testing to demonstrate that the relevant strains are present. No other FMD virus serotype registered on the manufacturing site should be present in the vaccine, to be assured by appropriate tests such as serotype-specific RT-PCR.

4.4. Purity testing

Purity relates to the level of FMD NSPs in the final product, which should not induce antibodies that would interfere with serological tests used for sero-surveillance of virus circulation in vaccinated populations. Products claiming to be purified from NSPs have to demonstrate their level of purification. Lack of reactivity has to be demonstrated in the final product (see Section C.5. *Requirements for registration of vaccine*). In cases where consistency of purification is demonstrated and approved in the registration dossier, and the production process is approved for consistency in accordance with the standard requirements referred to in chapter 1.1.8, the Veterinary Authority may agree to omit the test in the final product.

Confirmation of vaccine purity may be shown by testing sera from animals vaccinated at least twice with the batch for absence of antibodies to NSPs.

4.5. Safety testing

The safety of the final product should be proven batch to batch. The safety testing is conducted to detect any abnormal local or systemic adverse reactions. In cases where consistent safety of the product is demonstrated and approved in the registration dossier and the production process is approved for consistency in accordance with the standard requirements referred to in chapter 1.1.8, Veterinary Authority may agree to omit the test in the final product.

Safety could be checked in animals used for the potency test. Animals are inoculated by the recommended route of administration with the recommended dose of vaccine. When potency is assessed by PGP or EPP, all animals are observed for local and systemic reactions to vaccination for the 30 days duration of the potency test. When PD_{50} test is used, at least two healthy sero-negative target animals inoculated as above are observed for local and systemic reactions to vaccination for no fewer than 14 days. Any undue reaction attributable to the vaccine should be assessed and may prevent acceptance of the batch.

4.6. Potency testing

Potency is examined on the final formulated product, or alternatively for antigen banks on a representative batch of vaccine prepared from the same bulk inactivated antigen.

The potency testing standard is the vaccination challenge test. However, indirect tests can also be used for practicability and animal welfare considerations, as long as correlation has been validated to expectancy of protection in the target animal. Frequently indirect potency tests include antibody titration after vaccination of target species. Alternative methods could be used if suitably validated.

Ideally, indirect tests are carried out for each strain for one species and each formulation of vaccine to establish correlation between the indirect test results and the vaccine efficacy.

4.6.1. Expected percentage of protection (EPP) (Maradei *et al.*, 2008; Periolo *et al.,* 1993)

The EPP estimates the likelihood that cattle would be protected against a challenge of 10,000 bovine infective doses after a single vaccination.

i) Individual sera collected 30–60 days post-vaccination using a full dose of the vaccine are required from a group of either 16 or 30 18–24 month-old cattle.

ii) This panel of sera and sera of two control cattle are tested for antibody titres to the homologous FMD vaccine strain in a LPB-ELISA or VN test (see Sections B.2.1 *Virus neutralisation* and B.2.3 *Liquid-phase blocking enzyme-linked immunosorbent assay*).

iii) The antigens used in the ELISA may be inactivated using BEI.

iv) The EPP is determined by reference to predetermined tables of correlation between serological titres and clinical protection[1] (Maradei *et al.,* 2008; Periolo *et al.,* 1993).

v) Batches with at least 75% EPP (with 16 vaccinated cattle) or at least 70% EPP (with 30 vaccinated cattle) are satisfactory for potency.

The presence of more than one serotype in a vaccine does not diminish the induction of antibodies against another serotype or the correlation of antibody titre with protection.

4.6.2. Other methods for evaluating protection

Other tests were published using different ELISA methods and VNT methods to indirectly evaluate the protection given by vaccines. Their results could be accepted only if a valid correlation with protection in relation to the vaccine strain being tested and the serological method being used has been scientifically demonstrated.

5. Requirements for registration of vaccine

5.1. Manufacturing process

For registration of vaccine, all relevant details concerning manufacture of the vaccine and quality control testing (see Sections C.1–4) should be submitted to the National Veterinary Authority. This information shall be provided from three consecutive vaccine batches with a volume not less than 1/3 of the minimum allowed industrial batch volume from the country of origin.

5.2. Safety

For the purposes of gaining regulatory approval, a trial batch of vaccine should be tested for local and systemic toxicity by each recommended route of administration in an *in-vivo* test in at least eight animals of each target species. Double dose (e.g. two injections) and repeat single dose (after 14 days) tests using vaccines formulated to contain the maximum permitted payload and number of antigens are recommended to be conducted. In total animals receive three injections. The animals are observed for local and systemic reactions to vaccination for no fewer than 14 days after each injection. Any undue reaction attributable to the vaccine should be assessed and may prevent acceptance of the vaccine by the National Veterinary Authority.

5.3. Efficacy

Vaccine efficacy is estimated in vaccinated animals directly, by evaluating their resistance to live virus challenge or indirectly through *in-vitro* testing using well established correlations. The uncertainty of measurement in tests should be taken into account when interpreting its significance (Goris *et al.,* 2008). Vaccine efficacy should be established for every strain to be authorised for use in the vaccine.

Live reference FMD viruses corresponding to the main vaccine virus strains used in the region are available under certain conditions from WOAH Reference Laboratories for FMD in the region and from the National Veterinary Authority. These reference viruses are stored at ultralow temperatures and are sent, in strict accordance with shipping regulations.

The stock of challenge virus to be aliquoted is prepared from lesions collected from at least two cattle above 6 months of age that have been recognised as free from FMDV antibodies. These animals are

1 The WOAH Reference Laboratory in Brazil can provide tables upon request

tranquillised, then inoculated intradermally in the tongue with the suspension in about 20 sites of 0.1 ml each. The vesiculated tongue tissue or other body parts and vesicular fluid is harvested at the peak of the lesions, approximately 2 days later.

Harvested tissue is macerated and a 2% suspension is prepared, filtered through a 0.2 μm filter, aliquoted and quickly frozen in the gas phase of liquid nitrogen; this constitutes the challenge virus stock. The infective titres of this stock are determined both in cell culture ($TCID_{50}$) and in two cattle (BID_{50}) (50% bovine infectious dose). Two tranquilised cattle are injected intradermally in the tongue with tenfold dilutions (1/10 through 1/10,000), using four sites per dilution. The cattle titrations are read 2 days later. Titres are usually above 10^6 $TCID_{50}$ for 0.1 ml and above 10^5 BID_{50} for 0.1 ml, calculated using the Spearman–Kärber method. The dilution for use in the cattle challenge test is 10 000 BID_{50} in a total volume of 2 × 0.1 ml and is injected intradermally in the upper surface of the tongue both for the PD_{50} test and PGP test.

5.3.1. PD_{50} test

The number of protective doses in a vaccine is estimated from the resistance to infectious virus challenge of animal groups receiving different amounts of vaccine. Cattle of at least 6 months of age, obtained from areas free from FMD that have not previously been vaccinated against FMD and are free from antibodies to FMDV should be used. Three groups of no fewer than five cattle per group should be vaccinated by the route recommended by the manufacturer. The vaccine should be administered at different doses per group by injecting different volumes of the vaccine. For example, if the label states that the injection of 2 ml corresponds to the administration of 1 dose of vaccine, a 1/4 dose of vaccine would be obtained by injecting 0.5 ml, and a 1/10 dose would be obtained by injecting 0.2 ml. These animals and a control group of two unvaccinated animals are challenged either 3 weeks (aqueous) or up to 4 weeks (oil) after vaccination with a suspension of bovine virus that is fully virulent and appropriate to the virus types in the vaccine. The challenge test is done by inoculating the equivalent of a total of 10,000 BID_{50} intradermally into two sites on the upper surface of the tongue (0.1 ml per site). Animals are observed for at least 8 days. Unprotected animals will show lesions at sites other than the tongue. Control animals must develop lesions on at least three feet. From the number of animals protected in each group, the PD_{50} content of the vaccine is calculated. There are a variety of methods for calculating PD_{50} but procedures based on the Kärber (1931) method are generally preferred when interpreting PD_{50} estimates calculated in this way. The vaccine should contain at least 3 PD_{50} per dose for cattle.

5.3.2. PGP test (protection against generalised foot infection)

For this method, a group of 16 FMD-seronegative cattle of 18–24 months of age, with the same characteristics described for the PD_{50} test, are vaccinated with a full bovine dose by the route and in the volume recommended by the manufacturer. These animals and a control group of two unvaccinated animals are challenged 4 weeks or more after vaccination with a suspension of bovine virus that is fully virulent and appropriate to the virus types in the vaccine. The challenge test is performed by inoculating the equivalent of a total of 10,000 BID_{50} intradermally into two sites on the upper surface of the tongue (0.1 ml per site). Animals are observed for 7–8 days. Unprotected animals will show lesions on the feet within 7 days after inoculation. Control animals must develop lesions on at least three feet. For routine prophylactic use, the vaccine should protect at least 12 animals out of 16 vaccinated. This test does not provide an estimate of how many protective doses are in a single vaccine dose but comparison between tests suggested that 12 protected out of 16 vaccinated and challenged animals correlates with 3 PD_{50} (Vianna Filho *et al.,* 1993).

5.3.3. Efficacy estimated by indirect tests

When direct challenge test are not available to estimates efficacy, National Veterinary Authority may decide to use indirect tests (such as VN or LPB-ELISA), provided there is a correlation determined between antibody level and protection against challenge with 10,000 BID_{50}.

5.3.4. Efficacy in other species

Efficacy tests in other target species, such as sheep, goats, pigs or buffalo are either different or not yet standardised. In general, a successful test in cattle is considered to be sufficient evidence

of the quality of a vaccine to endorse its use in other species. Under circumstances where a vaccine is produced for use primarily in a species other than cattle, it may be more appropriate to potency test the vaccine in that same species. With respect to sheep, goats and African (*Syncerus caffer*) or Asiatic buffalo (*Bubalus bubalis*), due to the often inapparent nature of the disease in these species, potency results from a cattle test may be a more reliable indicator of vaccine quality than attempting a potency test reliant on the detection of clinical signs in these other species.

5.4. Purity: testing for antibody against NSP

Viral circulation within a defined population can be assessed by testing for presence of antibodies against NSPs. Furthermore the WOAH *Terrestrial Animal Health Code* stipulates that a criterion for regaining FMD free status following an outbreak, if vaccine is used, is to test the vaccinated animals for antibodies against NSP. Likewise, countries wishing to be recognised as FMD free with vaccination must demonstrate the absence of virus circulation by showing that vaccinated animals are free from antibody to NSPs arising as a result of infection. Consequently, FMD antigens used to formulate vaccines that may be used in these circumstances should be purified to reduce the NSP content. In addition to providing supporting documentation on the processes involved in such purification, manufacturers should demonstrate lack of immunogenicity against NSPs as part of the licensing procedure in order to make such a claim on their product literature. When purity tests include the use of full vaccine doses, at least 8 cattle should be booster vaccinated at 28–30 days after first vaccination and tested for purity 28–30 days later. Up to one reactive animal at 28–30 days post-booster vaccination could be accepted. If more than two animals are reactive at 28–30 days post-booster vaccination, the batch should be rejected. If two animals are reactive, the manufacturers have the option to ask for a batch retest. A recommended test method that can be used is to vaccinate not less than 8 naïve cattle with a full dose of the vaccine containing the maximum number of strains and amounts of antigen permitted on the authorisation. Cattle should be vaccinated at least twice at 21- to 30-day intervals and then tested before each revaccination and 30–60 days after the last vaccination for the presence of antibody to NSPs using the tests described in Section B.2.4 *Nonstructural protein* (*NSP*) *antibody tests*. Negative results in NSP assays may support claims that the vaccine does not induce antibody to NSPs for the number of injections tested. These cattle may be the same as those used for the safety test described in Section C.5.2 *Safety*.

5.5. Duration of immunity

The duration of immunity (D.O.I) of an FMD vaccine will depend on the efficacy (formulation and antigen payload). As part of the authorisation procedure, the manufacturer should be required to demonstrate the D.O.I. of a given vaccine by either challenge or the use of a validated alternative test, such as serology using the same test and animals described in Section C.5.3 *Efficacy* tested at the end of the claimed period of protection, in compliance with Section C.5.3. D.O.I. studies should be conducted in each species for which the vaccine is indicated or the manufacturer should indicate that the D.O.I. for that species is not known. Likewise, the manufacturer should demonstrate the effectiveness of the recommended booster regime in line with these guidelines, usually by measuring the magnitude and kinetics of the serological response observed.

5.6. Stability

The stability of all vaccines, including oil emulsion vaccines, should be demonstrated as part of the shelf-life determination studies for authorisation.

The shelf life of conventional FMD vaccines is usually 1–2 years at 2–8°C. Vaccines should never be frozen or stored above the target temperature.

Stability should be tested using the same methods described in Section C.5.3 *Efficacy*, but vaccinating the animals at the end of the shelf life of the product.

5.7. Precautions (hazards)

Current FMD vaccines are innocuous and present no toxic hazard to the vaccinators. Manufacturers should provide adequate warnings that medical advice should be sought in case of self-injection of a vaccine.

6. Storage and monitoring of concentrated antigens

Chapter 1.1.10 provides international standards for vaccine banks.

The process of storing concentrated antigens at ultra-low temperature for later formulation into FMD vaccine as described in Section C.2, is a well established procedure for building stocks of immunogenic material ready to be formulated into vaccines in case of need. It not only forms the basis for the storage of antigens in a strategic reserve for emergency purposes, but allows the manufacturer immediate access to many different antigen strains that can be rapidly formulated and dispatched to the customer (Lombard & Fussel, 2007). Such stockpiling minimises delays subsequent to an order, particularly where a multivalent vaccine is requested. Another advantage of this procedure is that much of the quality testing can be completed well in advance of shipment. It is necessary to state that the concentrated antigens have to be controlled using standards indicated in Sections C.1–4.

6.1. Storage conditions

6.1.1. Facilities

It is important that all aspects of the storage of concentrated antigens conform fully to internationally accepted requirements such as those referred to in chapter 1.1.8. Housing, facilities and procedures should ensure the security of the stored antigen and prevent tampering, contamination or damage.

6.1.2. Containment of stored antigens

The dose numbers or volumes stored are an important consideration, particularly where a reserve is shared between WOAH Members and there is variation in number of doses perceived to be needed by each Member in an emergency. Where the requirement is for a large stockpile of a particular vaccine strain that can only be produced from several separate production runs, vaccine bank managers must consider the need to either formulate each lot into a representative final blend for testing purposes or mixing the individual batches, at some convenient point, for ease of formulating and/or testing.

The type of container used to hold antigen concentrate is important. Under ultra-low temperature conditions it is important to use containers made from materials that do not become brittle or fragile at a temperature range allowing for heat sterilisation and cold storage.

6.1.3. Labelling of stored antigens

The concentrated antigens do not need to be labelled according to final or finished vaccine requirements and may be labelled as “in process” materials. Under ultra-low temperature conditions, the method of labelling must be of a durable nature. From experience, wire tagging bottles is the most preferred option using a metal/plastic tag sizeable enough to allow the necessary detail. Such detail should include the antigen/vaccine strain, batch number, date received and should also include an individual container or stock number. This information should be clear to read and marked on the tag using an indelible marker pen. Storage records and positions of containers should be carefully maintained.

6.2. Monitoring of stored concentrated antigens

It is vitally important that antigen concentrates are optimally maintained and routinely monitored in order to have some assurance that they will be efficacious when needed. Therefore arrangements should be made to monitor these antigen concentrates on a routine basis and to include where necessary, and at appropriate time intervals, a testing regime to ensure integrity of the antigen component or acceptable potency of the final product.

146S quantification, vaccination serology or vaccination challenge studies can be used for monitoring FMD antigen banks. It is recommended to carry out these tests on receipt (year 0) and every 5 years thereafter.

To support these testing requirements for depositories of antigen, concentrates should include a number of small samples that are representative of the larger stock. Small aliquots/stocks of FMD

antigen have usually consisted of a volume representing approximately one milligram of antigen. These aliquots should be stored side by side with the bulk antigen,

7. Emergency release of vaccines prepared from concentrated antigens

In situations of extreme urgency and subject to agreement by the National Veterinary Authority, a batch of vaccine may be released before completion of the tests and the determination of potency if a test for sterility has been carried out on the bulk inactivated antigen and all other components of the vaccine and if the test for safety and the determination of potency have been carried out on a representative batch of vaccine prepared from the same bulk inactivated antigen. In this context, a batch is not considered to be representative unless it has been prepared with not more than the amount of antigen or antigens and with the same formulation as the batch to be released.

D. VACCINE MATCHING TESTS

1. Introduction

Appropriate vaccine strain selection is an important element in the control of FMD and is necessary for the application of vaccination programmes in FMD-affected regions as well as for the establishment and maintenance of vaccine antigen reserves to be used in the event of new FMD incursions. The decision to change or include new strains in vaccine formulations is a multifaceted process and, among other issues, experimental, epidemiological and field observations should be considered.

Vaccination against one serotype of FMDV does not cross-protect against other serotypes and may also fail to protect fully or at all against other strains of the same serotype. The most direct and reliable method to measure cross-protection is to vaccinate relevant target species and then to challenge them by exposure to the virus isolate against which protection is required. This will take account of both potency and cross-reactivity.

However, such an approach requires the use of live FMDV and appropriate biosecurity procedures and practices must be used. The facility should meet the appropriate level of biocontainment, determined by risk analysis as outlined in Chapter 1.1.4 *Biosafety and biosecurity: Standard for managing biological risk in the veterinary laboratory and animal facilities.* In addition to the safety concerns, this procedure is slow and expensive and requires specific expertise that is best available in WOAH Reference laboratories. The use of animals for such studies should be avoided where possible by the use of *in-vitro* alternatives.

A variety of *in vitro* serological methods can be used to quantify antigenic differences between FMDV strains and thereby estimate the likely cross-protection between a vaccine strain and a field isolate. Genetic characterisation and antigenic profiling together with epidemiological observations can also reveal the emergence of new strains for which vaccine matching may be required and, conversely, may indicate that an isolate is similar to one for which vaccine matching information is already available. Such tests should be carried out in laboratories that work according to the standard specified in chapter 1.1.4 and Chapter 1.1.5 *Quality management in veterinary testing laboratories*, preferably WOAH Reference Laboratories for FMD.

Shipping of samples should be in accordance with Chapter 1.1.3 *Transport of biological materials*.

Vaccine potency and booster doses may contribute to the range of antigenic cover provided by a vaccine. A highly potent vaccine that stimulates a strong immune response may give protection to heterologous viruses. Furthermore, booster doses of vaccine can increase efficacy and the subsequent breadth of antigenic cover provided by a given vaccine, although the onset of full protection may be delayed (Pay, 1984).

2. Selection of field viruses for vaccine matching

For vaccine matching, preferably, more than one representative isolate should be evaluated from any outbreak.

Viruses should be selected based on epidemiological information, for instance isolation at different stages of an outbreak, from different geographical locations, or from different hosts (Alonso *et al.,* 1987). Field evidence for a suspected lack of vaccine quality as shown by reduced apparent protection, is an important criterion for vaccine matching, but other reasons for apparent vaccine failure (inadequate coverage, inadequate cold chain, insufficient boosting, lack of complementary control measures, etc.) should be also thoroughly explored.

The serotype of the field isolate is usually determined by ELISA or CFT using type-specific serological reagents, although methods based on MAbs or genetic typing may also be used. If the number of viruses exceeds the capacity of the laboratory to carry out methods described in Section D.4 *Vaccine matching tests*, a pre-selection of isolates should be done.

In order to minimise the risk of missing a relevant sample, the pre-selection should be carried out using all the isolates received by the laboratory. The recommended approach is to engage in serological validated antigenic profiling methods using MAb ELISA or CFT. VP1 sequencing should be used to verify the genetic homogeneity of the virus isolate population and its genetic distance with respect to the available vaccine strains.

The emergence of a new virus strain may be characterised by rapid dissemination with many outbreaks, and isolates from such epidemics are a priority for vaccine matching. Furthermore, isolates showing prevalence within the outbreak are the best candidates for vaccine matching tests. Isolates showing important differences with vaccine strains and not prevalent within the outbreak should be monitored closely through active surveillance in the field.

3. Selection of vaccine strains to be matched

The serotype of the virus, the region of origin and any information on the characteristics of the field isolate and, as appropriate, the vaccine strain used in the region of origin, may give indications as to the vaccine strains to be selected for vaccine matching tests. The availability of reagents for matching to particular vaccine strains may limit the extent of testing that is possible. To avoid this problem it is expected that vaccine manufactures should provide, upon request of the vaccine purchaser and WOAH Reference Laboratories, post-vaccination sera produced during final product batch potency testing. It is also recommended that WOAH Reference Laboratories guarantee the availability of reference post-vaccination sera produced with relevant vaccine strains. Vaccine matching approaches have two purposes: first, to guide the selection of the most effective vaccine strain for use in a particular field circumstance, either routine prophylactic vaccination or emergency use, for which matching requirements are not necessarily the same; and second, to monitor, on an ongoing basis, the suitability of vaccine strains maintained in strategic antigen reserves.

4. Vaccine matching tests

The serological relationship between a field isolate and a vaccine virus ('r' value) can be determined by VNT, ELISA or CFT. One way testing is recommended (r_1) with a vaccine antiserum, rather than two way testing (r_2), which also requires an antiserum against the field isolate to be matched. *In-vitro* neutralisation may be more relevant to predict *in-vivo* protection by the vaccine than other measures of virus-antibody interaction. VNT using the chequer-board titration method or other layout can be undertaken based in the laboratory experience. ELISA depends on the availability of trapping and detector antibodies suitable to the field strains, but it is more reproducible than VNT and can be carried out with inactivated virus. CFT can be used as a screening method to select strains to be tested by VNT or ELISA. The reproducibility of VNT results can be improved by incorporating multiple virus dilutions into the test so that the virus titre can be determined accurately by logistical regression.

For either VNT or ELISA, post-vaccination sera should be derived from at least five cattle 21–30 days after primary vaccination and/or 21–30 days after booster vaccination. The titre of antibody to the vaccine strain is established for each serum. Sera are used individually or pooled, after excluding low responders (Mattion *et al.,* 2009).

4.1. Relationship between the field isolate and the vaccine strain

The recommended standard test is the VNT. The ELISA can also be used if suitable reagents are available or as a screening test. The CFT is suitable as a screening test to select strains to be analysed by VNT or ELISA.

4.1.1. Vaccine matching by two-dimensional (chequerboard) neutralisation test

This test uses antiserum raised against a vaccine strain. The titres of this serum against 100 $TCID_{50\%}$ of the homologous vaccine strain and the same dose of a field isolate are compared to estimate the immunological coverage of the vaccine strain in relation to the field virus. For the test each 100 µl of virus/serum mixture contains 100 $TCID_{50}$ of test virus.

4.1.1.1. Test procedure

The procedure is similar to that of the VNT (see Section B.2.1 *Virus neutralisation*).

Additional biological reagents are: monovalent 21–30 day post-vaccination bovine sera (inactivated at 56°C for 45–60 minutes), the homologous vaccine strain; and the test virus, a field isolate of the same serotype as the vaccine strain.

i) Field isolates are passaged on cell cultures until adapted to give 100% CPE in 24 hours. Passages should be kept to a minimum. When adapted, determine the virus titre (log_{10} $TCID_{50}$/ml) by end-point titration.

ii) For each test and vaccine virus a chequerboard titration is performed of virus against vaccine serum along with a back-titration of virus. Cells are added and incubated at 37°C for 48–72 hours after which time CPE is assessed.

iii) Antibody titres of the vaccine serum against the vaccine strain and field isolate for each virus dose used are calculated using the Spearman–Kärber method. The titre of the vaccine serum against 100 $TCID_{50}$ of each virus can then be estimated by regression. The relationship between the field isolate and the vaccine strain is then expressed as an 'r' value as:

$$r_1 = \frac{\text{reciprocal arithmetic titre of reference serum against field virus}}{\text{reciprocal arithmetic titre of reference serum against vaccine virus}}$$

4.1.1.2. Interpretation

Interpretation of the results of cross-reactivity tests: It has been generally accepted that in the case of neutralisation, r_1 values greater than 0.3 indicate that the field isolate is sufficiently similar to the vaccine strain so that use of a vaccine based on this strain is likely to confer protection against challenge with the field isolate. However, protection depends on both the cross-reactivity of antibodies elicited by the vaccine and the strength of the antibody response. The latter will be influenced by the potency of the vaccine and the number of doses given.

When deciding whether or not to use vaccines for which r_1 values lower than 0.3 are observed, factors to be considered include the availability of better matching vaccine strains, the potency of the vaccine and the potential for this to be increased to provide heterologous responses, the possibility of using additional booster doses, and the extent to which control of disease will be complemented by other zoosanitary measures or will be dependent on vaccination. The combined impact of potency and match can be estimated from the serological titre of the vaccine antiserum against the field virus, although correlating this precisely to protection requires a cross-protection test.

Alternatively, a suitable field isolate could be adapted to become a new vaccine strain.

Tests should always be repeated more than once. The confidence with which 'r' values can be taken to indicate differences between strains is related to the number of times that the examination is repeated. In practice, a minimum of at least three repetitions is advised.

4.1.2. Vaccine matching by expectancy of protection (EPP) determined by one-dimensional neutralisation test

Vaccine matching based on EPP values is widely used in South America where correlation tables are available for the vaccine strains used in the Region. This test uses antiserum raised against a vaccine strain (primo and booster vaccination). The titres of sera against 100 $TCID_{50}$/100 µl of sera/virus mixtures of the homologous vaccine strain and the same dose of a field isolate are compared to estimate the immunological coverage of the vaccine strain in relation to the field virus.

4.1.2.1. Test procedure

The procedure is similar to that of the VNT (see Section B.2.1 *Virus neutralisation*).

Additional biological reagents are: monovalent 21–30 day post-vaccination, and/or 21–30 day post-booster vaccination bovine sera (inactivated at 56°C for 45–60 minutes); the homologous vaccine strain; and the test virus, a field isolate of the same serotype as the vaccine strain. For regions where multivalent vaccines are used, it is advisable to use sera panels raised against the vaccine commonly used in the vaccination programme.

i) Field isolates are passaged on cell cultures until adapted to give 100% CPE in 24 hours. Passages should be kept to a minimum. When adapted, determine the virus titre (log_{10} $TCID_{50}$/ml) by end-point titration.

ii) For each test and vaccine virus, a titration of antibodies is performed against a fixed amount of virus (100 $TCID_{50}$ of virus/100 µl of mixture sera/virus), along with a back-titration of working virus. Sera/virus mixtures and virus back titration are incubated at 37°C for 60 minutes and then inoculated on to microplates with preformed cell monolayers. Each serum dilution is inoculated in four wells and at least six sera dilutions are used. Microplates are incubated at 37°C for 48 hours under CO_2 atmosphere after which time CPE is assessed.

iii) Antibody titres of the vaccine serum against the vaccine strain and field isolate are calculated using the Spearman–Kärber method. The titre of the vaccine serum against 100 $TCID_{50}$ of each virus can then be estimated and expressed per ml. Individual EPP values are determined for each individual neutralisation titre using predefined correlation tables, and then the mean of the EPP is calculated for each group of sera (vaccinated and booster vaccinated). The immunological coverage of the vaccine strain is expressed by the EPP value.

b) Interpretation

i) Interpretation of the results

To interpret the results it is necessary to have a correlation defined between *in-vitro* titres and *in-vivo* challenge protection against 10,000 BID_{50} of vaccine virus. In the PANAFTOSA experience with FMDV control and eradication programmes in South America, a mean EPP value of 75% in booster vaccinated animals indicates that the vaccine strain is suitable to be used together with appropriate field measures to control outbreaks with the field strain under test (correlation tables for O1, A24 and C3 are available upon request to PANAFTOSA).

4.1.3. Vaccine matching by ELISA

Similarly, the liquid-phase blocking ELISA described in Section B.2.3 is recommended for vaccine matching calculating the r_1 or EPP value.

4.1.3.1. Test procedure

The procedure is similar to that of the LPBE (see Section B.2.3 *Liquid-phase blocking enzyme-linked immunosorbent assay*).

Additional biological reagents are: monovalent 21–30 day post-vaccination and/or 21–30 day post-booster vaccination bovine sera (inactivated at 56°C for 45–60 minutes); the homologous vaccine strain; and the test virus, a field isolate of the same serotype as the vaccine strain. For regions where multivalent vaccines are used, it is advisable to use sera panels raised against the vaccine commonly used in the vaccination programme.

4.1.3.2. Interpretation

i) Interpretation of r1 results

It has been proposed that in the case of LPBE, r_1 values greater than 0.4 indicate that the field isolate is sufficiently similar to the vaccine strain so that use of a vaccine based on this strain is likely to confer protection against challenge with the field isolate. However, protection depends on both the cross-reactivity of antibodies elicited by the vaccine and the strength of the antibody response. The latter will be influenced by the potency of the vaccine and the number of doses given. When deciding whether or not to use vaccines for which r_1 values lower than 0.4 are observed, factors to be

considered include the availability of better matching vaccine strains, the potency of the vaccine and the potential for heterologous responses to be increased, the possibility of using additional booster doses, and the extent to which control of disease will be complemented by other zoo sanitary measures or will be dependent on vaccination.

ii) Interpretation of EPP results

To interpret the results it is necessary to have a correlation defined between *in-vitro* titres and *in-vivo* challenge protection against 10,000 BID_{50} of vaccine virus. In the PANAFTOSA experience with FMDV control and eradication programmes in South America, a mean EPP value of 75% in booster vaccinated animals indicates that the vaccine strain is suitable to be used together with appropriate field measures to control outbreaks with the field strain under test (correlation tables for O1, A24 and C3 are available upon request to PANAFTOSA).

4.1.4. Vaccine matching by CFT

The CFT preferably performed in a tube, can be used as a screening test to select those strains to be tested by VN or ELISA. The test is performed as described in Section B.1.2.4. Additional biological reagents are guinea-pig hyper-immune sera against vaccine strains. Sera antibody titre is determined against homologous virus and field strains. The r_1 value is calculated as previously described:

$$r_1 = \frac{\text{reciprocal arithmetic titre of reference serum against field virus}}{\text{reciprocal arithmetic titre of reference serum against vaccine virus}}$$

Interpretation of the results: it is generally accepted that r_1 values equal or greater to 0.25 indicate that the field isolate is sufficiently similar to the vaccine strain. Studies by VNT or ELISA need to be performed with selected strains to confirm suggested CFT classification.

4.2. Testing the fitness for purpose of a vaccine

The "r" value should not be used in isolation to select the most appropriate vaccine strain to be used in the field. Particularly when it suggests an insufficient match of a certain vaccine strain, the suitability of a vaccine based on such a vaccine strain could be demonstrated by a heterologous cross-protection challenge test carried out as described in Section C.4.3 *Identity testing* in animals vaccinated with a known vaccine and challenged with the (heterologous) field virus. Vaccinate at least seven cattle without FMD antibodies, with a commercial dose of the current vaccine to be used in the region. Between 28 and 30 days later, boost all these animals with a second commercial dose in the same conditions and vaccinate a second group of at least seven animals with the same vaccine dosage and same route. Challenge the two groups and two control animals (not vaccinated) 30 days later with the equivalent of a total of 10,000 BID 50% of the new field strain duly titrated. The results are valid if each of the two control animal shows podal lesions on at least three feet. Final results are reported either as the number of protected animals (without podal lesion) over the total number of animal per group, or by percentage of protection where 100% is the total number of animals used per group. If results in the group of once vaccinated cattle indicate a protection level under 50%, and in the group of twice vaccinated cattle, protection under 75%, the change for a more appropriate vaccine strain is recommended.

The use of the EPP method is possible when correlation studies have been performed for the vaccine strain. The EPP method proved to be useful in some regions of the world applied together with epidemiological observations and active surveillance in the field. This method measures the reactivity of a panel of post-vaccination antisera using either VNT or ELISA and relates the serological titres to the probability of protection, established through correlation tables associating antibody titres with protection against challenge of 10000 BID_{50} of the homologous vaccine strain.
